*“To all who love the God with a 1000 names
and respect science”*

Preface

Since the time of Ancient Greece science and religion have been closely related, at least epistemologically. For instance, as Bertrand Russell notes in *Wisdom of the West* (1959:13), perhaps the most important notion in Greek philosophy was the concept *logos*, meaning both *word* and *measure*. We believe there are few doubts that *logos* is one of the main concepts used in both contemporary theology and the sciences, including social and human sciences.

In *Religion and Science in Context*, Willem B. Drees argues, “there is not only a need for serious study of ‘Religion and Science’, as an object to be studied, but also for serious reflection *in* ‘Religion and Science’” (2010: 150). Scientists and scholars taking the debate seriously face the following questions. Firstly, the question of how to relate scientific theories and findings to questions of faith, meaning and purpose as raised by religions and theology. Secondly, the question of how to relate empirical questions and answers to ethical and existential questions and answers. It was through questions and reflections such as these together with the quest for an adequate understanding of the world that does justice to what it means to be a human being embedded in oneself, the world, and for many, in God, that led to the emergence of the new discipline “Science and Theology”. As the name suggests, academics working in this field are interested in both science and religion in one way or another. They may belong to the academic field of the natural sciences, the social sciences, the human sciences, theology or religious studies.

Science and Theology is ideally an intellectual venture that aims at informing scientists about the theological relevance of scientific research on religious phenomena as well as at informing theologians about the impact of scientific progress on religious hermeneutics. Seen as such, a specialization of the academic field of Science and Theology seems unavoidable. However, some esteemed voices have lately become concerned about some of the recent developments in this new discipline. There is some unease about the consequences of an excess of specialization, which would render this new field too “professional” and too far removed from the traditional interests and methods of scientific as well as theological communities. Another reason disciplines may distance themselves from the academic course of study of Science and Theology is the confusion with the academic programme called Theology of Science on the one hand and the programme of Scientific Studies of Religion on the other.

Nevertheless, in the last quarter century this new academic field has attracted scholars from a wide variety of disciplines. However, such enterprises come with questions. For example, exactly which disciplines are attracted and what do these disciplines have to contribute to the debate? Hence, in order to describe accurately the shape and character of a possible relation between science and religion, it is important to clarify the identities of the suggested participants in that relationship.

Nina Azari founded the Encyclopedia of Sciences and Religions. Her idea was to produce an encyclopedia that is complete and covers all currently self-identified distinctive academic disciplines and religious traditions, within and across a wide range of cultures worldwide. Furthermore, the idea was to provide a comprehensive, up-to-date picture of how the *Science and Religion* discourse or dialogue has thus far been treated. The encyclopedia was meant to provide a starting point for new lines of inquiry and an invitation for fresh perspectives on the possibilities for engagement between and across sciences and religions. In addition, the idea was to make the current (self-)identities of the proposed participants within Science and Religion accessible to the academic community, in order for scholarship to proceed fruitfully in that field. She was successful in recruiting several of the editors listed in order to cover as many disciplines and traditions as possible. However, it soon became apparent that the project was too big to be handled by only one editor in chief. Hence, in 2008 Anne L.C. Runehov became the second editor in chief, with responsibility for the non-scientific sections while Azari would manage the scientific sections. Unfortunately, Azari retired from the project in the fall of 2010. At that point, Lluís Oviedo, being the editor for the section on anthropology, became the second editor in chief. While taking stock of the project thus far a troublesome imbalance was discovered between the amount of assigned and submitted entries in the different sections. We also realized that the guidelines needed to be revisited. Then we realized that we needed to change the direction of the scope of the encyclopedia in order to launch this wonderful ship. In this regard, we are very grateful to Springer, especially to Willemijn Arts, Anita Fei van der Linden and Harmen van Paradijs, for organizing an editorial board meeting in January 2011 in Amsterdam. At the time of the meeting, all sections represented different stages of development and different academic levels as well as different degrees of relevance, consistency and completeness. Needless to say we were forced to make some drastic changes. The meeting had several advantages. Firstly, all the editors from different disciplines got to know one another and became a devoted team working on different aspects of one encyclopedia. Secondly, divided into several groups, we could redirect and finalize the contexts of the different sections in order for the encyclopedia to meet the necessary criteria. Thirdly, we had a renewed working plan and could reinstall deadlines. Finally, when we left Amsterdam, we knew we were back on track and we had regained confidence that we would finish this important project.

The next challenge came when we, the EiCs, had to perform the final proofreading of the entire encyclopedia. At such stage, we realized that we could have prevented yet another delay of the publication of the work, if we had been responsible for the whole process from the beginning and,

furthermore, had we known more about certain layout standards. The A–Z format, together with its extended cross-references, is indeed user-friendly. The problem was that the glossary terms, which originally provided additional information to the entry in question, also were alphabetically ordered throughout the encyclopedia and were thereby taken out of their original context. The result was, besides glossaries losing their original sense, we ended up with double and triple explanations of one and the same term written by different authors. Also, we discovered that some authors had explained the term already within the main entry and provided the explanation separately as a glossary term. Hence, we had to reorganize the glossaries by removing some, gathering some into a short entry, and reentering some in the main text where we found it to be relevant. What we also realized even more clearly was that some of the questions concerning the disciplines' or traditions' self-identification were redundant. More precisely, the questions concerned with identification as a science or a religion. Obviously, sciences are not religions and religions are not sciences. Hence, and in order not to postpone publication even more, we took the liberty to remove the clearly irrelevant answers to these questions. We sincerely hope that the result of our carefully performed final proofreading will be to the author's satisfaction.

What the Encyclopedia of Sciences and Religions provides

As mentioned above, in the last quarter century, the academic field of Science and Theology (Religion) has attracted scholars from a wide variety of disciplines. The question above was which disciplines are attracted and what do these disciplines have to contribute to the debate? In order to answer this question, the encyclopedia maps the (self)-identified disciplines and religious traditions that participate or might come to participate in the Science and Religion debate. This is done by letting each representative of a discipline and tradition answer specific chosen questions. They have to identify the discipline as a discipline or sub-discipline, or tradition or sub-tradition and also identify the disciplines in relation to the Science and Religion debate. Understandably representatives of several disciplines and traditions answered in the negative to the latter question. Nevertheless, they can still be important for the debate; indeed, scholars and scientists who work in the field of Science and Theology (Religion) may need knowledge beyond their own specific discipline. Therefore the encyclopedia also includes what are called general entries. Such entries may explain specific theories, methods, and topics. The general aim is to provide a starting point for new lines of inquiry. It is an invitation for fresh perspectives on the possibilities for engagement between and across sciences (again which includes the social and human sciences) and religions and theology. This encyclopedia is a comprehensive reference work for scholars interested in the topic of 'Science and Religion.' It covers the widest spectrum possible of academic disciplines and religious traditions worldwide, with the intent of laying bare similarities and differences that naturally emerge within and across disciplines and religions today. There are medium to long entries for all potentially relevant academic

disciplines and religious traditions worldwide. The A–Z format throughout affords easy and user-friendly access to relevant information. Additionally, a systematic question-answer format across all Sciences and Religions entries affords efficient identification of specific points of agreement, conflict, and disinterest across and between sciences and religions. The extensive cross-referencing between key words, phrases, and technical language used in the entries facilitates easy searches. We trust that all of the entries have something of value for any interested reader.

It has been a long journey but a very interesting one allowing for fishing in many seas. The journey is not completely over yet because as well as the hard-cover version there is also an internet version which is to be updated on a regular basis.

Acknowledgments

First, we are deeply obliged to the section editors who are not only experts in their field but who have done a tremendous job, far beyond the call of duty. Hence, thank you Anders Kraal (Theology), Brian Les Lancaster (Judaism), Carl Raschke (Humanities), Daniel Langton (Judaism), Dimitris Xygalatas (New and Contemporary Religions), Gisela Full (Buddhism and Eastern Religions), Hans Ferdinand Angel (Theology), Javier Leach (Mathematics), Kelly Bulkeley (New and Contemporary Religions), Max Garzon (Computer Sciences), Michael Agliardo (Sociology), Nader El-Bizri (Islam), Norbert Samuelson (Judaism), Ray Palouzan (Psychology), Stoyan Tanev (Physics), and Sungchul Ji (Biology and Chemistry).

Secondly, and naturally, we want to thank Nina Azari for initiating the idea of this encyclopedia.

This project would of course not have been possible without the support of a most competent team from Springer. Hence, our gratitude goes to Andrew Spencer, Anita Fei van der Linden, Daniel Quinones, Harmen van Paradijs, Mansi Seth, Marta Janicki, Michaela Bilic, Sasha Goldstein-Sabbah, Stephanie Huegler, and Willemijn Arts. In particular we want to thank Willemijn and Daniel. It has been a delight working with both of you.

Lastly, we want to thank our departments for supporting us and giving us all the facilities we needed: The Copenhagen University Faculty of Theology and the Pontificia Universita Antonianum.

To all the authors: we once again apologize for the delay and the worries this caused you.

Editors-in-Chief

Anne L. C. Runehov Department of Systematic Theology, Copenhagen University, Copenhagen, Denmark

Lluis Oviedo Antonianum University, Rome, Italy

Section Editors

Michael Agliardo, SJ, Ph.D. Department of Sociology, Loyola University Chicago, Chicago, IL, USA

Michael Agliardo, SJ, is assistant professor of sociology at Loyola University Chicago. He has taught in the areas of qualitative research methods, environmental sociology, and the sociology of religion. In 2011 he completed a study of environmental activism among American Catholic women religious funded by the Association for the Sociology of Religion, and more recently he has written on American Catholic mobilization in response to climate change. In his research explores the intersections between environmentalism and faith, theology and science, and scholarship and activism.

Hans-Ferdinand Angel Faculty of Catholic Theology, Karl-Franzens University, Graz, Austria

Katholisch-Theologische Fakultät, University of Graz, Graz, Austria

Hans-Ferdinand Angel studied theology, Latin, and history in Regensburg and Paris. He was professor at the Technical University Dresden, and since 1997, is professor of catechetical and religious education at the Karl-Franzens University Graz. He is one of the responsible leaders of the so-called Graz Process which is in charge of coordinating the ecumenical cooperation of universities within Europe. He was the organizer and leader of an international and interdisciplinary research project (2002 to 2006): "Understanding Religiosity." He is member of the advisory committee of the Initiative of Brain Research in Styria and one of the coordinators of the Credition Research Project. Publications of importance: *Naturwissenschaft und Technik im Religionsunterricht* (1988), *Computer im Pfarrbüro* (1990), *Der religiöse Mensch in Katastrophenzeiten* (1996) and *Religiosität* (2006).

Kelly Bulkeley The Graduate Theological Union, Area V (Religion and Psychology), Kensington, California, USA

Kelly Bulkeley, Ph.D., is a visiting scholar at the Graduate Theological Union in Berkeley, California. He earned a doctorate in religion and psychological studies from the University of Chicago Divinity School, an M.T.S. from Harvard Divinity School, and a B.A. from Stanford University. A former president of the International Association for the Study of Dreams and a senior editor of the APA journal *Dreaming*, he has written and edited several books on dream research. His recent works include *Dreaming in the World's Religions: A Comparative History* (New York University Press, 2008); *American Dreamers: What Dreams Tell Us about the Political Psychology of Conservatives, Liberals, and Everyone Else* (Beacon Press, 2008); and *Dreaming in the Classroom: Practices, Methods, and Resources in Dream Education* (SUNY Press, 2011). He is the director of the Sleep and Dream Database (SDDb), a digital archive and search engine designed to facilitate empirical dream research.

Nader El-Bizri Civilization Sequence Program, American University of Beirut, Beirut, Lebanon

Dr. Nader El-Bizri is an associate professor in the Civilization Sequence Program at the American University of Beirut. Previously, he was a principal lecturer (reader) at the University of Lincoln, and he taught at the University of Cambridge, the University of Nottingham, the London Consortium, and at Harvard University, in addition to holding a senior research position at The Institute of Ismaili Studies in London, and longstanding research affiliations with the Centre National de la Recherche Scientifique in Paris. He maintains active memberships in various international societies and acts as an elected council member of the Société Internationale d'Histoire des Sciences et des Philosophies Arabes et Islamiques (CNRS, Paris). Dr. El-Bizri's areas of research are Islamic intellectual history, phenomenology, and architectural humanities. He has published and lectured widely and internationally as well as contributed to various BBC radio and TV programs. He also serves on the editorial boards of publications by Oxford University Press, Cambridge University Press, Springer, I. B. Tauris, and E. J. Brill, and has acted as a consultant to the Science Museum in London, the Aga Khan Trust for Culture in Geneva, and the Solomon R. Guggenheim Museum in New York and Berlin. Besides his academic profile, he practiced as a professional architect in offices in London, Cambridge, New York, and Beirut.

Gisela Emma Full Institute of Transcultural Health Sciences, European-University Viadrina, Frankfurt (Oder), Germany

Dr. Gisela Emma Full is a research fellow at both the European-University Viadrina in Frankfurt (Oder), Germany, and the Samuelli-Institute of Brain, Mind and Healing, Alexandria, VA, European Office. Her research focuses on perception alterations through meditation practices, deconstruction of self-models, Buddhist philosophy, and mindfulness-based coaching.

She was trained as an educational scientist at the University of Würzburg and Münster, Germany, and has gained her Ph.D. in the field of cultural science on “The Emancipation of Mind.”

Max H. Garzon Department of Computer Science, The University of Memphis, Memphis, TN, USA

Max H. Garzon joined the University of Memphis in 1984 after finishing his Ph.D. in the area of theoretical computer science at the University of Illinois, Urbana. Early in his career, he did research on the complexity of symmetric computational memory structures for sequential computers and on the separation of sequential complexity classes. Later, his research focused on parallel and distributed computing, particularly on artificial neural networks. His current research focuses on interactive computing, broadly including parallel and distributed computing and human-computer interaction, both in the traditional areas and the emerging areas of biomolecular programming and bioinformatics. In addition to over 150 publications in these areas, including five books and numerous special issues of major journal publications, he has developed software products for complex systems simulation and control, such as *Edna* (a virtual test tube), early versions of *Autotutor* (an intelligent computer-based tutoring system for instruction in computer literacy and conceptual physics), online election systems, and a variety of software solutions for local business and industries, some as part of student internships and outreach projects. His research has been funded by NSF, AFOSR, and other agencies. He has enjoyed sabbatical collaborations during visits to various countries in Europe, Asia, and Latin America. He is a senior member of ACM, IEEE, and member of the editorial board of the *International Journal of Nanotechnology and Molecular Computing* and *Genetic Programming and Evolvable Machines*, among others.

Sungchul Ji Department of Pharmacology and Toxicology, Ernest Mario School of Pharmacy, Rutgers University, Piscataway, NJ, USA

Dr. Sungchul Ji received a Ph.D. degree in physical organic chemistry in 1970 from the State University of New York at Albany. After postdoctoral research and teaching experiences in enzymology (University of Wisconsin, Madison), biophysics (University of Pennsylvania), systems physiology (Max Planck Institute, Dortmund, West Germany), and toxicology (University of North Carolina School of Medicine, Chapel Hill), Dr. Ji joined the Department of Pharmacology and Toxicology at the Ernest Mario School of Pharmacy, Rutgers University in 1982, where he has been teaching theoretical pharmacology and computational/theoretical cell biology in addition to the interdisciplinary seminar courses focused on integrating physics, biology, and philosophy. Dr. Ji is the author of *Molecular Theory of the Living Cell: Conceptual Foundations, Molecular Mechanisms and Applications* published by Springer, New York, in April, 2012 and is currently working on two more books on the cell language theory and its applications to theragnostics and personalized medicine, to be published by The Imperial College Press, London, and Springer, New York, respectively.

Anders Kraal Department of Philosophy, University of British Columbia, Vancouver, Canada

Dr. Anders Kraal was born 1979 in Nanaimo, Canada, and currently resides in nearby Vancouver. In 2007–2008, he was a Fulbright fellow at the University of Notre Dame in the USA. He holds multiple degrees from Sweden's Uppsala University, including a Ph.D. in philosophy, an M.A. in logic and metaphysics, another M.A. in religious studies, a B.A. in the history of science and ideas, and a bachelor's degree in theology. He currently holds a postdoctoral research position in philosophy at the University of British Columbia, Canada, where he is working on the problem of evil.

B. Les Lancaster School of Natural Sciences & Psychology, Liverpool John Moores University, Liverpool, UK

B. Les Lancaster is emeritus professor of Transpersonal Psychology at Liverpool John Moores University, honorary research fellow at the Centre for Jewish Studies of the University of Manchester, and adjunct research faculty at the Institute of Transpersonal Psychology and the California Institute of Integral Studies. He is currently chair of the Transpersonal Psychology Section of the British Psychological Society and President of the International Transpersonal Association. Les' research interests focus on the cognitive neuroscience of consciousness and the psychology of mysticism, with a specific focus on Kabbalistic psychology. In addition to various journal articles, Les' published works include *Mind Brain and Human Potential*, winner of a Science and Medical Network Best Book Award; *The Elements of Judaism*; *Approaches to Consciousness: the Marriage of Science and Mysticism*; and *The Essence of Kabbalah*.

Daniel R. Langton Department of Religions and Theology, University of Manchester, Manchester, UK

Daniel R. Langton is professor of the history of Jewish-Christian relations at the University of Manchester and codirector of its Centre for Jewish Studies. He is secretary of the European Association for Jewish Studies and coeditor of the Jewish Studies journal *Melilah*. The focus of his research is the history of Jewish-Christian relations and modern Jewish thought, and he is currently writing on Jewish theological engagement with Darwinian Theory. His main publications include *Claude Montefiore: His Life and Thought* (Vallentine Mitchell, 2002), *Children of Zion: Jewish & Christian Perspectives on the Holy Land* (Woolf Institute, 2008), *The Apostle Paul in the Jewish Imagination* (Cambridge University Press, 2010), *Writing the Holocaust* (coedited with Jean-Marc Dreyfus, Bloomsbury, 2011), and *Normative Judaism? Jews, Judaism and Jewish Identity* (coedited with Philip S. Alexander, Gorgias Press, 2012).

Javier Leach Facultad de Informática, Departamento de Sistemas Informáticos y Programación, Complutense University of Madrid, Madrid, Spain

Javier Leach has been director of the Chair of Science, Technology and Religion at the Universidad Pontificia Comillas since its creation in 2003 till 2011. Currently he is also professor at the School of Computing of the Universidad Complutense de Madrid. He has degrees in philosophy, mathematics, and theology. In 1977, he obtained the title of Doctor in Mathematics from the Universidad Complutense de Madrid. Since 1987, he has been professor at the Universidad Complutense in the area of computer languages and systems at the Computer Science Faculty.

Lluís Oviedo Antonianum University, Rome, Italy

Lluís Oviedo is currently full professor of Christian anthropology and issues of science and theology at the Antonianum University in Rome and invited professor in the Theological Institute of Murcia (Spain) for questions of faith and reason. He has published the books *Secularization as a Problem* (1990); *Altruism and Charity* (1998); *The Christian Faith and the New Social Challenges* (2002), and about 140 scholarly articles in the interfaces between theology, philosophy, sociology, and science. He has edited the academic journal *Antonianum* and is now an editor of *ESSSAT News*, bulletin of the European Society for the Study of Science and Theology. At the moment, his research focuses on cognitive science of religion and its theological impact, and issues about secularization process and religious social dynamics.

Raymond F. Paloutzian The International Journal for the Psychology of Religion, Westmont College Psychology Department, Santa Barbara, CA, USA

Raymond F. Paloutzian received his Ph.D. in 1972 from Claremont Graduate School and is professor emeritus of experimental and social psychology at Westmont College, Santa Barbara, California. He taught at Scripps College of The Claremont Colleges and has been a visiting professor teaching psychology of religion at Stanford University. He is a fellow of the American Psychological Association (divisions of general, teaching, social issues, psychology of religion, and international psychology), the Association for Psychological Science, and the Western Psychological Association. Dr. Paloutzian was honored to serve as president of the American Psychological Association Division 36 (Psychology of Religion and Spirituality). He wrote *Invitation to the Psychology of Religion*, 2nd ed., (Allyn & Bacon, 1996, 3rd ed. forthcoming), and coedited with Ani Kalayjian *Forgiveness and Reconciliation: Psychological Pathways to Conflict Transformation and Peace Building* (Springer, 2009/2010). Dr. Paloutzian and Crystal Park edited the *Handbook of the Psychology of Religion and Spirituality*, 2005, 2nd ed. 2013 (Guilford publishers). He has been guest professor and continuing visiting scholar, Faculty of Psychology, Katholieke Universiteit Leuven, Belgium. Dr. Paloutzian is editor of *The International Journal for the Psychology of Religion*.

Carl A. Raschke Department of Religious Studies, University of Denver, Denver, CO, USA

Carl Raschke is professor of religious studies at the University of Denver, specializing in continental philosophy, the philosophy of religion, and the theory of religion. He is an internationally known writer and academic, who has authored numerous books and hundreds of articles on topics ranging from postmodernism to popular religion and culture to technology and society. His latest book, entitled *Postmodernism and the Revolution in Religious Theory: Toward a Semiotics of the Event* (University of Virginia Press, 2012), looks at the ways in which major trends in Continental philosophy over the past two decades have radically altered how we understand what we call “religion” in general. His previous two books – *GloboChrist* (Baker Academic, 2008) and *The Next Reformation* (Baker Academic, 2004) – examine the most recent trends and paths of transformations at an international level in contemporary Christianity.

Other well-known works include *Painted Black* (HarperCollins, 1991), which surveys the relationship between certain religious cults and violence in contemporary society; *The Interruption of Eternity* (Nelson-Hall, 1980), regarded as a standard reference work on the origins of the New Age movement; *The Digital Revolution and the Coming of the Postmodern University* (Routledge, 2002), an analysis of the online revolution in higher education; *Fire and Roses: Postmodernity and the Thought of the Body* (State University of New York, 1995), a study of what the term “postmodernism” means in a broad theoretical and cultural perspective; and *The Engendering God* (Westminster, 1995), an investigation of “feminist” strains in early Bible and early Christianity.

Raschke is also past-president and former executive director of the American Association for the Advancement of Core Curriculum and past director of the University of Denver’s Institute for the Humanities. He has also served on the board of directors as well as various national committees of the American Academy of Religion. He is cofounder and senior editor of *the Journal for Cultural and Religious Theory*. He has been a frequent news commentator on religion and contemporary culture as well as higher education. He is also a permanent adjunct faculty at The Seattle School of Theology and Psychology. He holds a Ph.D. from Harvard University.

Anne L. C. Runehov Department of Systematic Theology, Copenhagen University, Copenhagen, Denmark

Anne L. C. Runehov has a reader (associate professor) degree from the Uppsala University and currently works as a guest senior researcher at the Department of Systematic Theology at the Copenhagen University. She earned a doctor's degree in philosophy of religion at Uppsala University, and a master's degree in theoretical philosophy, major philosophy of mind, at the same university. Her degrees also include Psychology, History of science and ideas, and Law.

She is editor-in-chief for the series *Copenhagen University Discussions in Science and Religion*, Faculty of Theology publications, Copenhagen. Coeditor for this series is Professor Charles Taliaferro. She is also field editor for the *European Journal of Science and Theology*. She is the author of *Sacred or Neural? The Potential of Neuroscience to Explain Religious Experiences* (2007), which is based on her doctoral thesis for which she received the 2006 ESSSAT research prize. Furthermore, she is the director of the *Copenhagen Network for Science and Religion*, funded by the John Templeton Foundation. She has published several peer-reviewed articles. Runehov has mainly (but not merely) been working within the debate of Science and Philosophy of Religion. Her main research interests have been neuroscience, cognitive science, and quantum mechanics, which are studied from the perspective of philosophy of religion, philosophy of mind, epistemology, and philosophy of science. She has contributed to radio and TV programs within Scandinavia and was interviewed various times for newspapers and magazines.

Norbert M. Samuelson School of Historical, Philosophical, and Religious Studies, Arizona State University, Tempe, AZ, USA

Norbert M. Samuelson is the Grossman Chair of Jewish Studies at Arizona State University in the Department of Religious Studies. He is an internationally renowned scholar of Jewish philosophy, who is the author of 12 books and over 200 articles. His published books that deal directly with questions of science and Judaism are *The First Seven Days: A Philosophical Commentary on the Creation of Genesis* (1992), *Judaism and the Doctrine of Creation* (1994), *Revelation and the God of Israel* (2002), and *Jewish Faith and Modern Science* (2009).

Professor Samuelson has been active in the American Academy of Religion, the Association of Jewish Studies, the American Philosophical Association, Metanexus, the International Society for Science and Religion, and the Franz Rosenzweig Gesellschaft.

Rüdiger J. Seitz Department of Neurology, Heinrich-Heine-University, Düsseldorf, Düsseldorf, Germany

Rüdiger J. Seitz is professor of neurology and vice chairman of the Department of Neurology at Heinrich-Heine-University, Düsseldorf, Germany. He was research fellow of the German Research Council on motor learning and somatosensory processing at the Brain Imaging Center at the Karolinska Institute, Stockholm, Sweden, 1987–1989. He is head of the Functional Neuroimaging Research Laboratory with an interest in stroke recovery and control of behavior. He was awarded the Hugo-Spatz Award of the German Neurological Society in 1992 and served as chairman of the 5th International Conference on Functional Mapping of the Human Brain, Düsseldorf, in 1999. He was distinguished fellow at the Institute of Advanced Study, LaTrobe University, Bundoora, Victoria, Australia, in 2006–2007 and became honorary professorial fellow, Florey Neuroscience Institutes, Melbourne, Australia, in 2009.

Stoyan Tanev Integrative Innovation Management, Department of Technology and Innovation, University of Southern Denmark, Odense M, Denmark

Dr. Stoyan Tanev is an associate professor in the Department of Technology and Innovation and member of the Integrative Innovation Management (I²M) Research Unit at the University of Southern Denmark (SDU), Odense, Denmark. Before joining the Department of Technology and Innovation at SDU in August 2009, Dr. Tanev was a faculty member in the Technology Innovation Management Program, Department of Systems and Computer Engineering, Carleton University, Ottawa, Ontario, Canada. Dr. Tanev has an M.Sc. in physics from Sofia University (1989); an M.Eng. in technology management from Carleton University, Canada (2005); and an M.A. from University of Sherbrooke, Canada (2009). He also has a Ph.D. in physics (1995, jointly from the University of Sofia, Bulgaria, and the University Pierre and Marie Curie, Paris, France) and Ph.D. in theology from Sofia University (2012). His research interests are in technology innovation management, value co-creation, and human creativity. Dr. Tanev's research interests include also the history of Eastern Christian thought with a focus on the modern history of the Orthodox Church. Last but not least, Dr. Tanev is interested in epistemological issues of relevance for both science and the philosophy of religion.

Dimitris Xygalatas LEVYNA Laboratory for the Experimental Research of Religion, Masaryk University
Department of Culture and Society, Aarhus University, Aarhus, Denmark

Dimitris Xygalatas is Director of the LEVYNA Laboratory for the Experimental Research of Religion in Brno, and holds a joint position between Aarhus University in Denmark and Masaryk University in the Czech Republic. He received his Ph.D. from the Institute of Cognition and Culture at Queen's University Belfast and subsequently held postdoctoral positions at the universities of Princeton and Aarhus.

Xygalatas is an experimental anthropologist. His research focuses on high-intensity rituals and their effects on the individual and the social level. He has conducted several years of fieldwork in Southern Europe and Mauritius, using novel methodologies combining ethnographic and experimental techniques to study some of the most extreme rituals in the world.

His books include *The Burning Saints: Cognition and Culture in the Fire-walking Rituals of the Anastenaria* (London: Equinox 2012), and (with William McCorkle) *Mental Culture: Classical Social theory and the Cognitive Science of Religion* (London: Acumen 2013). He is a founding member of the International Association for the Cognitive Science of Religion and Managing Editor of the *Journal for the Cognitive Science of Religion*.

A

A Priori Arguments

► [Ontological Arguments](#)

A Priori/A Posteriori

Neil Spurway
University of Glasgow, Glasgow, Scotland, UK

Terms used to distinguish concepts existing in the mind independently of, and hence before (*a priori*), any experience from those only formed on the basis of, and so after (*a posteriori*), the experiences to which they relate. Immanuel Kant, in particular, held that it is only in terms of *a priori* ideas that we can make sense of experience; by contrast empiricists, such as John Locke, contended that all concept-formation was contingent upon, and so *a posteriori* to, experience.

Description

Abhidhamma (Pāḷi) (<http://www.abhidhamma.com>; <http://www.abhidhamma.org>) is the third division or basket (*piṭaka*) of the *Tipiṭaka* or Pāḷi canon, the foundation of Theravāda Buddhism. While similar, slightly different kinds of Abhidharma (Sanskrit) belong to the various Mahāyāna traditions or to the Hinayāna schools, the latter having perished already. “Abhidhamma” literally means the higher or special teaching (of the Buddha). It is a huge collection of systematically arranged, tabulated, and scientifically classified teachings of the Buddha, representing the quintessence of his teachings, timeless and independent of culture, race, and gender. Abhidhamma is the Buddhist philosophy,

describing the reality and truth completely. Abhidhamma is also the Buddhist psychology, dealing mainly with mental phenomena and explaining in detail how the mind works and how it can be liberated.

In the discourses (*sutta*), the Buddha takes into consideration the intellectual level of his audience, their development of the perfections (*pāramī*), their attainments, and the specific situation. He therefore teaches the dhamma in conventional terms and relative concepts (*paññatti*), referring to persons and objects as I, he, she, man, woman, cow, tree, etc. In the Abhidhamma, however, the Buddha does not make such concessions, but is treating the dhamma entirely in terms of the ultimate reality (*paramattha*). All phenomena are analyzed into their ultimate constituents (*dhamma*) which are precisely defined, classified, and systematically arranged. Then, the laws of interaction between the dhammas are taught, their synthesis – a net of conditionality.

The Abhidhamma Piṭaka ([Nyanatiloka](#)) consists of seven books:

1. Dhammasaṅgaṇī – Enumeration of the dhammas, “Buddhist Psychological Ethics”

Description of the fundamental, ultimate mental, and physical phenomena constituting human experience.

2. Vibhaṅga – “The Book of Analysis”

Exposition of the analysis in the Dhammasaṅgaṇī in form of a catechism with many references in Suttanta.

3. Dhātukathā – “Discourse on Elements”

Description of the 18 elements in sets of questions and answers. Similar substance like Dhammasaṅgaṇī and Vibhaṅga.

4. Puggalapaññatti – “A Designation of Human Types”

Description of the qualities of individuals and personality types. By differentiation, suitable teachings and meditation subjects can be given individually.

5. Kathāvatthu – “Points of Controversy”

Collection of questions and orthodox answers in order to show superiority and distinguish Theravāda from other schools (compiled by Moggaliputta Tissa in the third century B.C.).

6. Yamaka – “The Book on Pairs”

Twisted and vice versa Abhidhamma questions and answers for deep understanding.

7. Paṭṭhāna – The Book of Conditions or “Conditional Relations”

Explanation of the 24 forces working between cause or condition and effect. Describing the laws of interaction of the dhammas analyzed in Dhammasaṅgaṇī, this is the great synthesis.

Self-Identification

Science

Abhidhamma, which presents itself as very abstract, profound, logical, and scientific, should not be looked upon as all theory and pure scholasticism. Abhidhamma stems from empirical knowledge of the Buddha which he acquired by his full enlightenment. It describes the full range of knowledge, insight, and human experience with all and everything. Studying Abhidhamma can be compared with studying a map, but the map has to be used; one has to travel in order to reach the destination or, rather, to achieve one’s goal. Abhidhamma alone is just abstract science. It has to be applied in daily life and meditation.

Religion

Abhidhamma is to some extent religion in which one is supposed to believe or have confidence in, as long as one has not yet experienced it oneself. But the more one can prove by own experience with clear, sharpened mind, especially in Vipassanā meditation, the more confidence (*saddhā*) will arise in one’s mind. The Buddha himself did not talk of his teachings as religion, and encouraged and urged to accept and believe only what practically turns out as wholesome and beneficial for liberation. People turned the dhamma into a religion called “Buddhism.” Buddhism, and especially Abhidhamma, has nothing to do with a creator god or a god responsible for our life and fate. To the contrary, Abhidhamma clearly explains about life, death, rebirth, *kamma* and its result, and all causality-conditionality. Therefore, it can be seen as

a doctrine transcending death and giving its followers meaning in life, sense, guidelines, and understanding.

Albert Einstein is ascribed to have said: “The religion of the future will be a cosmic religion. It should transcend a personal God and avoid dogmas and theology. Covering both the natural and the spiritual, it should be based on a religious sense arising from the experience of all things, natural and spiritual as a meaningful unity. If there is any religion that would cope with modern scientific needs, it would be Buddhism” (Quotation ascribed to Einstein according to: <http://www.spaceandmotion.com/Albert-Einstein-Quotes.htm>, referring to Albert Einstein (1954)). Most probably Einstein did not come into contact with Abhidhamma, which would have been a wonderful supplementation and enrichment.

Characteristics

While other religions have to be accepted because of a god, heavenly messenger, or prophet, Buddhism and Abhidhamma are to be accepted and practiced only if, when tested, lead to wholesome states, more happiness, calmness, serenity, mental peace, and liberty (Essence of the popular Kālāma Sutta, Collection of Gradual Discourses, A III. 66). One follows according to one’s own level of insight and understanding.

While traditions and religious teachings, including most of the Buddha’s discourses (*sutta*), give practical guidelines and explanations to concrete persons in various, distinct circumstances, cultures, and eras which might no longer be suitable for our present age and problem, Abhidhamma – with its ultimate realities (*dhamma*) – offers a complete, abstract picture so that we can find our own answers for an ethical and wholesome life, for mental development, and for understanding the world and seeing things as they really are. All other religions and common philosophies rely on a soul or self (*atta*) in one way or another and follow personality belief either with eternity or annihilation views, while the Buddha taught nonself, soullessness (*anatta*) and Abhidhamma can be regarded as a huge compendium on *anatta*.

Relevance to Science and Religion

Abhidhamma, explaining things and phenomena according to the experience of the fully enlightened Buddha, does not need a proof by science and also does not fear science or any new results from research. There can never be a contradiction. Abhidhamma encourages scientific research, and some modern Abhidhamma scholars and practitioners are interested in related sciences, like physics (especially quantum physics), neurology, psychology, modern ways of psychotherapy, and research in the field of meditation, psychosomatic diseases, and working of the brain, mind, and memory.

Sources of Authority

There is the story or legend in the Theravāda tradition that states Abhidhamma was first taught by the Buddha for 3 months in the 7th year after his enlightenment in *Tāvātimsā* heaven to deities including the Buddha’s departed mother, who had been reborn there. Ven. Sāriputta, one of his main disciples and second in knowledge after the Buddha, had received a brief summary each day from the Buddha himself. Then, Ven. Sāriputta formulated and arranged what we call Abhidhamma today and taught it to a selected group of his monk-pupils, who were ready to grasp it. Sāriputta might be the real author indeed, since he is known through the *suttas* as a very analytical, sharp-minded person. His excellent knowledge and way of explanation were praised by the Buddha himself.

Modern Buddhologists, linguists, and historians claim that the Abhidhamma is a later work. Traditional Buddhists deny this and maintain that at least the essence of the Abhidhamma goes back to the Buddha himself, while later rearrangements and rewording found in the books are of minor importance. All six Buddhist councils, the first was held just 3 months after the Buddha’s death, up to the latest international council from 1954 to 1956, have reexamined, accepted, and confirmed the Abhidhamma Piṭaka as authentic and correct. An exception is the

fifth Abhidhamma book, Kathāvatthu, which definitely is more recent and was included during the third council under King Asoka in 246 B.C. (Nyanatiloka).

Further, Abhidhamma is consistent with and does not contradict the Suttanta, but systematizes and explains the manifold contents of the *suttas* in greater detail.

Last but not least, Abhidhamma gets its natural authority by being confirmed and proved true by generations of meditators according to their own experience.

Ethical Principles

Ethics and morality are the basics and foundation of Abhidhamma. Without an ethical lifestyle as foundation, no insight, attainment, or realization is possible. In the Abhidhamma, all phenomena (*dhamma*) are classified according to their ethical qualities, which additionally have to be kammically wholesome in the sense of leading in the right direction toward goodness and liberation. The traditional system of classification of consciousness and mental states therefore differentiates between wholesome, unwholesome, and kammically variable or neutral states. Abhidhamma always stresses their difference, their origination, and their impact. Without blaming unethical persons or behaviors, without dos and don'ts, the Abhidhamma just teaches the abstract facts of these wholesome and unwholesome physical, verbal, or mental actions. It is up to everyone which path to follow, ethical or unethical, but one should know the effects – not only for others but also for oneself. One who really understands and penetrates Abhidhamma will definitely train oneself and lead an ethical life.

Key Values

Key values according to Buddhism are ethics (*sīla*), concentration (*samādhi*), and wisdom (*paññā*), which together form the Noble

Abhidhamma, Southern, Fig. 1 Constituents of the Noble Eightfold Path

Eightfold Path (*ariya aṭṭhaṅgika magga*), leading to the cessation of suffering (Fig. 1).

Abhidhamma teaches all three values systematically and in the ultimate sense. Being a Buddhist psychology, Abhidhamma analyzes the connected mental states, the circumstances and conditions which lead to their arising, or, in the case of ethics, the right mental attitude and motivation in order to behave ethically.

Some factors of the Noble Eightfold Path, like concentration and effort, can be either wholesome or unwholesome. The Abhidhamma offers criteria how to differentiate and decide, which one should be developed, and which one should be abandoned.

The purpose of struggling and developing these values is the final goal of liberation, the attainment of *Nibbāna*. The way is shown as a step-by-step process through increasing insight and knowledge and by penetrating the realities or, rather, experiences, and through realizing them as impermanent (*anicca*), as suffering or unsatisfactory (*dukkha*), and as nonself or uncontrollable (*anatta*). The Abhidhamma aims specifically at the understanding of *anatta*.

Conceptualization

Nature/World

Abhidhamma has a realistic view. The world is made up of animate and inanimate things. According to the Abhidhamma, inanimate things such as mountains, rocks, trees, tables, or books are made up of matter only, of various material qualities or physical phenomena (*rūpa*). Animate or living beings consist of mind and matter (*nāmarūpa*). These various mental and physical phenomena comprising beings and the world are taught in detail in their origination and relation in Abhidhamma. The conditional relations of phenomena, following natural laws, are seen in the interrelationship and dependence among beings and in the whole nature. Therefore, to care for the nature, the environment, and others will in turn lead to caring for oneself. Nature is not seen as perfect, but because of its characteristic of impermanence (*anicca*), unsatisfactoriness (*dukkha*), and nonself (*anatta*), nature belongs to the conditional world (*Samsāra*) and is tied to the endless cycle of arising and dissolving, of birth and death.

Human Being

A human being is mainly differentiated from other beings by its rebirth consciousness (*paṭisandhi citta*), which is a direct product of its previous wholesome kamma. The Abhidhamma describes 31 planes of existence in the world; only one is human, and only two, human and animal, planes can be perceived by us. Productive *kamma* decides where and as what kind of being one is reborn. It is said, as a human being, one has the best chances for mental development and liberation because there is much freedom in decision. In this plane, various types of *kamma* can ripen and produce results; usually a mixture of happiness and suffering is experienced that can motivate one to struggle and train the mind.

Life and Death

Life or a living being is characterized in the Abhidhamma by two phenomena called life faculty (*jīvitindriya*) (**Bodhi**; **Tin Mon**). There is

physical life or physical vitality in the material groups, which has the function to protect the coexisting matters from rotting and decay. It is a direct and immediate product of *kamma* and makes the difference between the body of a living person and a human corpse. The other life phenomenon is mental or psychic life or psychic vitality, which is a mental factor (*cetasika*) associated with all types of consciousness (*citta*) and various kinds of mental states. Its function is to protect the coexisting mental phenomena within the same mental unit for a certain tiny lifespan. The great majority of beings consist of mind and body, having both mental and material life. Some beings of the higher planes of existence consist of mind only, without bodies, having only mental life. Then, there is a rare unconscious being (*asaññasatta*) in higher planes of existence who has no mind but is made up of matter only, having at least material life.

How is it that there are all these different beings and types of life? They are all results of various and quite different *kamma* performed in previous lives. The higher planes and life without body, that is, only mind, or without mind, that is, only body, are reached through intense meditation, through attaining and mastering the various meditative absorptions (*jhāna*) and through special aspirations.

For the birth – or rather conception – of a human being, three things have to coincide: Mother and father, that is, ovum and sperm, need to be present and, as main factor, a kammic impulse from a just departed being. The death of a being once again has to do with kamma. Death, that is, the cutting off of the individual lifestream of a being, may happen because of four reasons according to Abhidhamma:

1. End of lifespan (differs for species and in epochs)
2. End of kammic energy of the life-producing *kamma*
3. Case 1 and 2 together
4. A destructive *kamma* which intervenes and cuts off the energy of the life-producing *kamma*

Abhidhamma, Southern,**Fig. 2** Reality according to Abhidhamma**Reality according to Abhidhamma**

Conditioned realities (<i>sāṅkhata dhammā</i>)				Unconditioned realities (<i>asāṅkhata dhammā</i>)
Conventional realities Conventional realities/concepts (<i>paññatti</i>) conventional truth (<i>sammuti sacca</i>)		Ultimate realities Ultimate realities (<i>paramattha dhammā</i>) or ultimate truth (<i>paramittha sacca</i>)		
<i>nāma-paññatti</i> name of a thing, phenomenon, person or being	<i>attha-paññatti</i> thing, person or being itself	<i>nāma</i> mind, mentality, mental / psychic phenomena <i>citta</i> (89/121) = consciousness <i>cetasika</i> (52) = mental factors, mental states, mental qualities	<i>rūpa</i> matter, body, corporeality, material / physical phenomena 28 <i>rūpas</i> : 4 great elements, 5 sense-organs, sense-objects, etc.	<i>Nibbāna</i> 1. <i>kilesa-nibbāna</i> = <i>sa'upadisesa</i> <i>Nibbāna</i> 2. <i>khandha-nibbāna</i> = <i>anupadisesa</i> <i>Nibbāna</i>
Objects for <i>Samatha</i> meditation		Objects for <i>Vipassanā</i> meditation Universal characteristics: <i>anicca, dukkha, anatta</i>		Object in the enlightenment (<i>magga + phala</i>) Characteristic: <i>anatta</i>

Death caused by case 1–3 is called timely death, while case 4 is called untimely death, which might happen even at young age by a fatal accident or a life-threatening disease.

The Abhidhamma gives minute explanations about the working of *kamma* and the mental death and rebirth processes. *Kamma* performed or remembered just before dying has a great chance to produce the next life. In that way, Abhidhamma even proves the benefit of modern hospice work by providing guidelines to relatives or nurses who accompany a dying person.

Reality

Abhidhamma is a science of reality or rather “realities.” First, there is the differentiation into conventional and ultimate reality or truth. In daily life, we deal only with concepts (*paññatti*) which are essential in the field of ethics, loving kindness (*mettā*), compassion, etc.

To see with Abhidhamma or “Vipassanā eyes” means to see the ultimate realities (*paramattha dhammas*) (Boriharnwanaket) behind the facade of concepts and to penetrate through to their characteristics in order to let go, detach, and liberate the mind.

Second, reality is twofold: conditioned and unconditioned. Whatever phenomena, things, beings, and states – they are all conditioned.

The only unconditioned reality is *Nibbāna* (Sanskrit: *Nirvāna*).

Abhidhamma deals with ultimate reality, conditioned and unconditioned. (<http://www.abhidhamma.com>) Ultimate realities are what really can be experienced by the six senses directly. The Abhidhamma distinguishes four ultimate realities:

1. Consciousness (*citta*)
2. Mental factors (*cetasika*)
3. Matter (*rūpa*)
4. *Nibbāna*

These four kinds of reality are again classified manifold. Abhidhamma enumerates 170 (or 202, if consciousness is classified into 121) different realities (Fig. 2).

These ultimate realities are ultimate in the sense that their characteristics do not change, whenever they are present, not that they are permanent themselves. For example, anger is not permanently with us, but whenever anger arises, it presents itself with the same typical distinguishing features. Each ultimate reality has its specific, individual characteristic, manifestation, and function. Therefore, each reality is defined exactly and, in practical experience, can be distinguished clearly by a sharp, well-trained mind. Universal characteristics of all ultimate, conditioned realities are:

- Impermanence (*anicca*)
- Unsatisfactoriness or inherent suffering (*dukkha*)
- Nonself (*anatta*)

In contrast, *Nibbāna*, the only unconditioned reality, has the characteristics of permanence and satisfactoriness or happiness (*sukha*). Yet, as the conditioned phenomena, *Nibbāna* too has the characteristic of nonself (*anatta*).

Knowledge

Different kinds of knowledge are differentiated in Abhidhamma (Bodhi; Tin Mon): knowledge by own thinking (*cinta mayā ñāṇa*), book knowledge or knowledge by listening (*anubodha-ñāṇa* or *suta mayā ñāṇa*), and direct knowledge by own, intuitive, and penetrative insight (*paññā* or *bhāvanā mayā ñāṇa*), the latter being the most important and transforming knowledge, which includes insight knowledge (*Vipassanā ñāṇas*). Meditators have to go through these insight steps in order to attain *Nibbāna*. Only the Buddha himself is awarded omniscience (*sabbāññūta-ñāṇa*).

Knowledge (*ñāṇa*) or wisdom (*paññā*) is one of the “beautiful” mental factors (*sobhana cetasikas*), which can associate only with wholesome and beautiful types of consciousness. It definitely should be developed and included in all actions. If knowledge is associated with beautiful mental factors, then the kammic quality of a wholesome action becomes stronger and better. Furthermore, in Abhidhamma we learn that only people with a kammically acquired rebirth consciousness associated with knowledge can attain meditative absorptions (*jhāna*) and may attain *Nibbāna*, that is, path and fruition consciousness (*maggā* and *phala citta*).

Truth

Truth is often mentioned in the same sense as reality. However, conventional truth and ultimate truth are differentiated. The dhamma is attributed truthfulness (*svakhata*) and timelessness (*akalika*), that is, it is a teaching according to the truth, giving ever true replies to questions about suffering, its origin, and its cessation, and describing solution of existential problems of past times as well as today.

Speaking about truth in Buddhism implies speaking about the Four Noble Truths, the quintessence of the Buddha’s teachings. They are explained in greater detail in the doctrine of dependent origination (*Paṭiccasamuppāda*) which is clearly explained in the Abhidhamma too (Nyanatiloka; Bodhi; Tin Mon; Buddhaghosa b, c) (Fig. 3).

The first noble truth of suffering is found in the second and fourth section of the circle comprising the phenomena conventionally called birth, decay, death, sorrow, lamentation, pain, suffering, and despair. In terms of ultimate truth, they are phenomena like resultant consciousness (*viññāṇa*), mind and matter (*nāmarūpa*), sense bases (*saḷāyatana*), contact (*phassa*), and feeling (*vedanā*), which are the kammic results (*vipāka*) that we have to face.

The second noble truth of the origin of suffering is found in the first and third section of the circle: Ignorance (*avijjā*) and kamma formations (*saṅkhāra*) are mentioned as past causes for suffering, craving (*taṇhā*), clinging (*upadāna*), and active, kammic process of becoming (*kamma-bhava*). Indeed all these factors worked in past, work in present, and will work in future as a natural law – as long as we have not yet found and used the exit. In this way, *Paṭiccasamuppāda* explains *Samāsāra*, the endless cycle of cause and effect of suffering. Summarizing it can be said that Kamma produces its results (*vipāka*) with the help of mental defilements (*kilesa*), like ignorance and craving. The way to stop suffering, that is, painful, undesirable results, is not to stop actions (*kamma*), but to eradicate the defilements (*kilesa*) (Fig. 4).

This cessation of suffering or the end of the cycle of *Samāsāra* is *Nibbāna* – the third noble truth. And the path to achieve this practically is the Noble Eightfold Path, which constitutes the fourth noble truth. These are fundamental truths in conformity with natural laws.

Perception

Perception (*saññā*) according to Abhidhamma (Bodhi; Tin Mon; Boriharnwanaket; Buddhaghosa b, c) is a universal mental factor (*cetasika*), that is, it associates with all types of

Abhidhamma, Southern,
Fig. 3 Dependent
Origination

Abhidhamma, Southern, Fig. 4 Cycling in Samsara

consciousness. It is the awareness of an object's distinctive marks. If, through repeated perception of an object, these marks are recognized, *saññā* functions as memory. Sometimes *saññā* can mislead if it compares a new, similar object with the memorized marks of a previous object.

Perception is sometimes used for the whole mental unit including consciousness. But still, an object cannot be fully perceived or known clearly by just one mind moment, one single unit of sense perception, which is conditioned by the sense organ and its corresponding object.

Abhidhamma commentaries (Bodhi; Tin Mon; Dhamma 2007) explain that at least four mental processes (*vīthi*s) are necessary to be able to know and name the object which, for example, was seen in the first process only. Each process is made up by 17 or 12 mind moments, respectively, following each other in fixed and reasonable series.

Usually people say and think “I perceive” or “myself perceives this and that.” Yet, according to Abhidhamma only bare processes are running, conditioned by certain circumstances. There is no perceiver, no observer, no creator, no soul, or no self behind it. Just impersonal processes devoid of I or self.

Time

Time is a concept that – according to Abhidhamma – is relative and is derived from changeability, impermanence, and movement in phenomena. “Chronological time (*kāla*), denoted by reference to this or that event, is merely a conventional expression....Since it has no existence in itself, one has to understand it as a mere concept (Atthasālinī, §58–59, commentary by Buddhaghosa to Dhammasaṅgaṇī, the first of the seven Abhidhamma books).” Albert Einstein

puts it tersely: "Time is what one reads from the clock (Quotation ascribed to Einstein)." The measurement of time is possible only because of the movement of the hands relative to the clock's face or by marking events or certain states in changes: birth and death, sunrise and sunset, and appearance of a phenomenon and its disappearance. The shortest time span that can be defined according to Abhidhamma is the duration of one of the three submoments of consciousness: (1) the arising submoment, (2) the existence or standing submoment, and (3) the falling or vanishing submoment. All three together form one mind moment, that is, the lifespan of consciousness. Seventeen times longer than that is the lifespan of matter.

In Abhidhamma and its commentaries, past, future, and present times are defined precisely for the material and mental phenomena or the five aggregates (*khandhā*) respectively according to four points: period of time (*addhā*), continuity of a process (*santati*), occasion (*samaya*), and moment (*khaṇa*) (Buddhaghosa b, c) (Path of Purity (Visuddhimagga), XIV, §494 or §472/473 in most translations).

Concerning *Nibbāna*, the unconditioned reality, the concept of time becomes meaningless and cannot be applied.

Consciousness

Consciousness (*citta*) is one of the four ultimate realities in Abhidhamma (<http://www.abhidhamma.com>; <http://www.abhidhamma.org>; Bodhi; Tin Mon; Boriharnwanaket; Dhamma 2007; Buddhaghosa a, b, c). It is that which is aware of an object or cognizes the object. Consciousness always has an object; it might be a present sense object or a mental object, a thought or a memory.

Throughout life there is consciousness, one consciousness after the other without gap, but only one consciousness a time. Even when someone is "unconscious" like in coma or when fainted, a subtle, passive type of consciousness (*bhavaṅga*) is present. Therefore, it is spoken of a "stream of consciousness" which flows continuously according to its conditions from birth to death and continues in the next life (*citta*

santāna); this continuous stream will cease only in the attainment of the final *Nibbāna*. This individual stream of consciousness follows a fixed, defined sequence as natural law (*citta niyāma*).

Consciousness does not arise alone, but always together with at least seven mental factors (*cetasika*), which together constitute the mind (*nāma*). Consciousness is compared to clean, clear water which cannot be seen. Only by added colors or dirt, water becomes visible. In the same way, consciousness can be perceived by its "colors" only – the mental factors (*cetasika*) – which arise simultaneously with the same object but with different characteristic and function.

According to the six senses as bases, there are six types of consciousness:

1. Eye consciousness
2. Ear consciousness
3. Nose consciousness
4. Tongue consciousness
5. Body consciousness
6. Mind consciousness

These are conditioned essentially by the sense organ and its respective object, when they come into contact with each other.

In Abhidhamma, 89 types of consciousness are known; however, another classification shows 121 types (Fig. 5) (<http://www.abhidhamma.com>).

Consciousness is classified into four groups according to plane or sphere, where it predominately occurs (Rewata Dhamma 2007):

1. Sense sphere consciousness
2. Fine material consciousness
3. Immaterial consciousness
4. Supramundane consciousness

Consciousness is also divided into four classes according to its nature:

1. Unwholesome consciousness
2. Wholesome consciousness
3. Resultant consciousness
4. Functional consciousness

Furthermore, within these classes, consciousness often is classified according to roots, feeling, association, and promptitude.

Consciousness arises and dissolves in a person at a tremendous rate of more than 1,000 billion

Nibbāna is not possible to describe and explain. Surely, one cannot get or imagine the taste of something of which one does not have any experience. However, Abhidhamma offers a description which can be grasped and understood intellectually, although one has not yet tasted it (Bodhi; Tin Mon; Boriharnwanaket).

Nibbāna literally means end of craving (*vāna*). As craving is the main cause for suffering (*dukkha*), which is already taught in the Four Noble Truths of the Buddha, the end of craving is the cessation of suffering, and that is *Nibbāna* (Boriharnwanaket).

Nibbāna, deathlessness, the unconditioned, is an ultimate reality beyond impermanence and beyond suffering and even any latent suffering or unsatisfactoriness. *Nibbāna* is peace, is stillness, is neither coming nor going. There are two types of *Nibbāna*, and they should be distinguished precisely. *Nibbāna* means extinguishing, fading away. The type of *Nibbāna* the Buddha had realized in his enlightenment is *Kilesa Nibbāna*, the irreversible extinguishing of the mental defilements (*kilesa*). However, mind and matter still remain and follow their own processes. This type is called “*Nibbāna* with rest” (*sa-upādisesa Nibbāna*). In the other type of *Nibbāna*, there is no rest, no remainings (*an-upādisesa Nibbāna*), and this is *Khandha Nibbāna*, characterized by the extinguishing of the five aggregates (*khandha*), that is, mind and matter.

The common saying “*Nibbāna* is the highest bliss” can be explained in various ways. While the mind takes *Nibbāna* as object, there are sublime happiness and peace. Also, having attained *Nibbāna*, the person experiences a great feeling of release and is filled with happiness because one knows that one has attained it and that there will be no more suffering and rebirth. However, the enlightened person still has body and mind which oppress one and which are naturally bound to decay. Only the cessation of body and mind – even the good, happy states, and emotions – is bringing total stillness and peace; that is the highest bliss indeed.

This final state is eloquently summarized in the Buddha’s famous phrase:

Impermanent, alas, are all conditioned phenomena,
They have the nature of arising and decay,
Having been born, they vanish.
Their calming is true happiness (“*Aniccā vata saṅkhārā, uppāda vata dhammino, uppajjitvā nirujjhanti, tesam vūpasamo sukho.*” *Dīghanikāya*: Collection of Long Discourses, D16 and D17).

Description

The Abhidharma is a system aiming at a systematic analysis and proper understanding of the Buddha's teachings. Its origin is to be traced to the *sūtra*-s. The northern tradition of Abhidharma is mainly represented by the Sarvāstivāda – or its orthodox camp known as the Vaibhāṣika, based mainly in Kaśmīra – and the Sautrāntika. In fact, it is these two schools that later Indian philosophical texts typically mention as the “Abhidharma” or “Hīnayāna” schools of thought. Around seventh or eighth century C.E., the Sāṃmitīya – a branch of the Vātsīputrīya – came into prominence as

a leading Hīnayāna school, more or less eclipsing the Sarvāstivāda. However, both the Sautrāntikas (and their forerunner, the Dārṣṭāntikas) and the Vātsīputrīyas originally descended from the broad Sarvāstivāda lineage, so that an understanding of the Sarvāstivāda doctrines as representative of the northern Abhidharma tradition is indispensable.

Like the Theravādins, the Sarvāstivādins too maintain that the *abhidharma* was taught by the Buddha himself. But unlike the Theravādins who claim that the whole set of their canonical Abhidhamma texts was authored by the Buddha, the Sarvāstivādins ascribe their seven canonical texts to individual authors: (1) *Dharma-skandha* by Śāriputra, (2) *Śāṅgīti-paryāya* by Mahākauṣṭhila, (3) *Prajñāpti-sāstra* by Mahāmaudgalyāyana, (4) *Vijñānakāya* by Devaśarman, (5) *Prakaraṇa-sāstra* by Vasumitra, (6) *Jñānaprasthāna* by Kātyāyanīputra, and (7) *Dhātukāya* by Pūrṇa. Of these, the first three belong to the earlier period, and the rest may be grouped under the later period. The *Jñānaprasthāna* was upheld as the supreme authority by the Vaibhāṣikas who called it the “body,” in contrast to the other six which were called the “feet.”

The Meaning of “Abhidharma”

On the term “*abhidharma*,” in the developed Abhidharma system represented by the period of the Abhidharma treatises, firstly, “*abhi-*” in the sense of “facing directly” (*abhimukha*) signifies direct realization (*abhisamaya*) into the true nature of *dharma*-s. This is the meaning of the definition that “*abhidharma* is outflow-free (*anāsrava*) or pure *prajñā*” (2, 2), where both *abhidharma* and *prajñā* are defined as “investigation/discernment of *dharma*-s” (*dharma-pravicaya*). Secondly, “*dharma*” here does not mean “Doctrine,” but refers either to the ultimate reals, each having a unique intrinsic nature (*svabhāva*) and being uniquely experienced as an intrinsic characteristic (*svalakṣaṇa*), or to *Nirvāṇa* as the *Dharma par excellence* (2, 2). In the *Abhidharma-mahāvibhāṣā* (compiled around

150 C.E.), the Sarvāstivāda master Buddhapālita explains the signification of “*abhi-*” thus:

“*abhi-*” is a prefix signifying “*abhimukha-*.” This *dharma* is called *abhidharma* because it induces all skillful *dharma-s*—the factors conducing to Enlightenment (*bodhi-pakṣa-dharma*)—to manifest directly. (3, 4b22–25)

Abhidharma as pure *prajñā* defines *abhidharma* in the highest or absolute sense. We can also speak of *abhidharma* in the conventional sense as comprising all that serves as the means for the acquisition of this pure *prajñā* (2, 2). In the northern Abhidharma, *prajñā* does not refer exclusively to pure wisdom; it represents the faculty of understanding which can be pure or impure, proper or improper, correct or erroneous, etc. Abhidharma in the conventional sense then includes the various forms of impure or with-outflow (*sāsrava*) understanding – possessed by an ordinary worldling (*prthagjana*) – derived from listening (*śruta-mayī*), from reflection (*cintā-mayī*), from cultivation (*bhāvanā-mayī*), and from birth (*upapatti-prātilambhikā*) – as well as the Abhidharma texts that serve as the means for the development of the pure *prajñā*.

The definitional identification of “*abhidharma*” with “*prajñā*” spells out the central importance of the latter as both the means and the ultimate aim of *abhidharma* investigation. This is more explicitly shown in the definition of *prajñā* in the *Abhidharmadīpa-prabhāvṛtti* (1, 70) and Skandhila’s *Abhidharmāvatāra*:

Understanding (*prajñā*) is the discernment of *dharma-s*. It is the examination (*upalakṣaṇa*), as the case may be, of the following eight kinds of *dharma-s*: inclusion (*saṃgraha*), conjunction (*saṃprayoga*), endowment (*samanvāgama*), causes (*hetu*), conditions (*saṃgraha*), effects (*phala*), intrinsic characteristic (*svalakṣaṇa*), common characteristic (*sāmānyalakṣaṇa*). (5, 83)

The eight items enumerated constitute the fundamental topics as well as methodological devices of the Ābhidharmikas.

- 1–2. “Intrinsic characteristic” and “common characteristic.” These two constitute the core concern of *dharma-pravicaya*, so much so that Abhidharma in a gist may in fact be defined as the methodological

study of intrinsic and common characteristics of the real existents (*dharma*) within and outside the sentient being.

3. “Conjunction” studies the dynamic relationship between the simultaneously existing mental factors.
4. “Inclusion” is an important device for determining the nature of *dharma-s* in terms of their intrinsic natures:

For instance, the visual faculty is subsumed under the matter-aggregate, by the visual abode (*caḥsur-āyatana*) and the visual element (*caḥsur-dhātu*), and the truths of unsatisfactoriness and origin. This is because they constitute its intrinsic nature. It is not [subsumed under] the other aggregates, etc., for it is distinct in nature from them. (2, 12)

- 5–7. Every *dharma* is both a cause/condition for other *dharma-s* and is also caused/conditioned by other *dharma-s*; the study of causality (“causes,” “conditions,” and “effects”) is therefore of fundamental importance.
8. “Endowment” – a modality of acquisition (*prāpti*) – is a special topic, also of fundamental importance to the Sarvāstivāda system (see below).

From the perspective of the above definition of *prajñā/abhidharma*, an “Ābhidharmika,” i.e., a specialist in the Abhidharma, may be succinctly defined as one who specializes in the study of these eight topics.

The Five Fundamental Categories Comprising 75 *Dharma-s*

The totality of the ultimate reals arrived at by the Ābhidharmika-s are subsumed under the traditional “five-aggregates” (*pañca-skandha*) scheme, plus the group of three unconditioned *dharma-s*:

- (1) Matter (*rūpa*); (2) sensation (*vedanā*); (3) ideation (*saṃjñā*); (4) conditionings (*saṃskāra*), divisible as the conjoined conditionings (*saṃprayukta-saṃskāra*, i.e., the thought-concomitants other than sensation and ideation) and the disjoined conditionings (*viprayukta-saṃskāra*); and (5) consciousness (*viññāna*). The three types of unconditioned (*asaṃskṛta*)

dharma-s are (6) cessation through deliberation (*pratisaṃkhyā-nirodha*), (7) cessation independent of deliberation (*apratisaṃkhyā-nirodha*), and (8) space (*ākāśa*).

A more commonly adopted scheme of classification is that of the five fundamental categories, innovated by Vasumitra in his *Prakaraṇa-pāda*. A total of some 75 *dharma-s* are subsumed under this scheme:

1. *Matter (rūpa)*: visual faculty, auditory faculty, olfactory faculty, gustatory faculty, tangible faculty, visual object, auditory object, olfactory object, gustatory object, tangible object, noninformative matter (*avijñapti-rūpa*)
2. *Thought (citta)*
3. *Thought-concomitants (caitasika-dharma)*
 - (a) Ten universal *dharma-s* (*mahā-bhūmika*): sensation, volition, ideation, predilection, contact, understanding, mindfulness, mental application, resolve/determination, equipoise
 - (b) Ten skillful universal *dharma-s* (*kuśāla-mahābhūmika-dharma*): faith, diligence, calm, equanimity, modesty (*hrī*), shame (*apatrāpya*), nongreed, nonhatred, harmlessness, vigor
 - (c) Six universal *dharma-s* of defilement (*kleśa-mahābhūmika-dharma*): delusion, nondiligence, slackness, lack of faith, torpor, restlessness
 - (d) Two unskillful universal *dharma-s* (*akuśāla-mahābhūmika dharma*): nonmodesty (*āhrikyā*), shamelessness (*anapatrāpya*)
 - (e) Ten defilements of restricted scope (*parīttakleśa-bhūmika dharma*): anger, enmity, dissimulation, jealousy, depraved opinionatedness (*pradāśa*), concealment, avarice, deceptiveness, pride, harmfulness
 - (f) Eight indeterminate *dharma-s* (*aniyata dharma*): remorse, sleep, reasoning, investigation, greed, hostility, conceit, doubt
4. *Conditionings disjoined from thought (cittaviprayukta saṃskāra dharma)*: acquisition (*prāpti*), nonacquisition (*aprāpti*), group homogeneity, ideationlessness, ideationless attainment, cessation attainment, vital faculty, production-characteristic,

duration-characteristic, deterioration-characteristic, impermanence-characteristic, words, phrases, syllables

5. *Three unconditioned dharma-s (asaṃskṛta-dharma)*: cessation through deliberation, cessation independent of deliberation, space

Remarks on the Five-Category Classification

1. Matter comprises the four Great Elements (*mahā-bhūta*) and the derived matter (*upādāya-rūpa, bhautika*).

Under this category, there is an item known as the noninformation matter, which is a special doctrine of the Sarvāstivāda school. This is a special type of *rūpa*, being invisible, nonresistant, and nonspatialized. Nevertheless, it is said to be of the nature of matter since its supporting basis (*āśraya*) – the four Great Elements – are resistant matter. This is the medium of preservation of the karmic efficacy projected from a momentary bodily or vocal *karma*. It is “noninformative” because it is a karmic action that does not inform us of the mental state of its doer. At the time when an information (*viññapti*) *karma* – namely, a bodily or vocal *karma* – is accomplished, the corresponding *avijñapti* is projected as an invisible force in which the karmic efficacy is preserved. Once projected, it continues to exist as a series until either the corresponding karmic effect is retributed or when a certain condition is met with – such as the person’s death. In the course of development, it came to be particularly emphasized as the karmic efficacy projected when one solemnly takes an ordination vow (*saṃvāra*; “restraint”); e.g., of abstaining from killing (2, 8, 205, 208, etc.). But even when its serial continuity has been terminated by reason of the person’s death or his giving up the ordination vow, etc., the karmic efficacy is not lost. In the Sarvāstivāda tenet of the tritemporal existence of *dharma-s*, the said *avijñapti* continues to exist in its past mode of being (*bhāva*). The difference between a serially continuing *avijñapti* that always arises in the present and one that has become past is that,

unlike the former, the latter's karmic status has come to be fixed and subsequently no more capable of being continuously interacted upon – and thus modified – by the person's actions. Nevertheless, as a past *dharma*, it is still efficacious in contributing to the actual giving of the corresponding effect at a future time.

The Sautrāntikas deny that the *avijñapti* is a real entity. They hold that, as the Buddha has taught, all *karma* is volition (*cetanā*), and a karmic force of the nature of matter is unimaginable and unacceptable. For them, the preservation of karmic efficacy is to be explained in terms of a progressively transformed serial continuity projected from the initial volition (see below).

2. The Sarvāstivādins hold that (1) thought and the thought-concomitants (such as sensation, ideation, etc.) are distinct real entities and (2) no thought or thought-concomitant can arise singly – they necessarily arise in conjunction (*samprayoga*). For instance, any thought necessarily arises with the set of ten universal thought-concomitants. When a skillful thought-concomitant arises, it necessarily does so together with the thought involved, the set of ten universal *dharma*-s and the set of ten skillful universal thought-concomitants (faith, etc.).

A conjunction presupposes a fivefold sameness or equality (*samatā*): The thought and thought-concomitants (1) arise at the same time, (2) share the same basis (*āśraya*), (3) take the same cognitive object (*ālambana*), (4) have the same mode of activity/understanding (*ākāra*), and (5) each has a singularity of substance (*dravya* – e.g., a single thought conjoined with a single species of sensation, a single species of ideation, etc.).

The Dārṣṭāntikas in the *Abhidharma-mahāvibhāṣā* maintain that mental factors arise sequentially, rather than simultaneously. Among them, Buddhadeva teaches that the so-called thought-concomitants are none other than thought itself. Dharmatrāta and others concede that there are three distinct thought-concomitants – sensation, ideation, and volition – all other “thought-concomitants” are merely different modalities of volition. The 4th C.E. Dārṣṭāntika-Sautrāntika master, Śrīlāta, vehemently opposes

the Sarvāstivāda conception of the simultaneous existence of distinct thought-concomitants.

3. The category of “conditionings disjoined from thought” is not found in the Theravāda and other schools. It represents an Abhidharma development that recognizes the existence of a third category of reals, beyond the matter–mind duality. Although these disjoined forces are neither physical nor mental, they can nonetheless exercise efficacies in both domains.

Their nature and function are best illustrated with the example of “acquisition” (*prāpti*), a force which links a *dharma* – whether physical or mental, conditioned or unconditioned – to a sentient being. Thus, when, say, a sensual craving arises in the sentient being, he comes to “possess” this *dharma* called sensual craving, which has always been existing in the universe, thanks to this force, “acquisition,” which as it were ties (like a rope) the craving to him. The acquisition of this craving, once projected, serially flows on in the person even when the craving does not arise manifestly – e.g., when the person's mental stream is of a skillful or neutral nature. For this reason, he is continuously possessed of this craving. When, as a result of spiritual praxis, the person comes to be freed from (to “abandon,” *pra-√hā*) this craving, it is not that the *dharma* called craving as an ontological entity comes to be destroyed but, rather, that the serial continuity of its acquisition is cut off from him.

When one comes to attain *Nirvāṇa*, it cannot be that the unconditioned *dharma* arises as an effect of a path which is conditioned (see below). What is produced by the path is the acquisition (itself a conditioned *dharma*) of the *Nirvāṇa*, which links the latter to the practitioner.

In this way, we see that through the operation of acquisition, the ever-existent *dharma*-s come to be linked to the domain of the sentient. It is also as much a *sine qua non* for the explanation of the process of pollution (*saṃkleśa*) as for purification (*vyavadāna*) and even the attainment of *Nirvāṇa*.

4. For the Sarvāstivādins, not only are the conditioned *dharma*-s pluralistic, the unconditioned

dharma-s as well, are pluralistic. They are the only *dharma*-s that can be truly said to be “permanent” (*nitya*), because they alone transcend time and space. Even the “intrinsic natures” of *dharma*-s, which retain their integrity throughout time, are impermanent. There are three types of conditioned *dharma*-s:

- (a) Cessation through deliberation. This is a cessation brought about through an effort of understanding (*prajñā*; *pratisaṃkhyā* is explained as *prajñā-viśeṣa*) the true nature of defilement. This cessation is a real entity, not a mere absence of the defilement. It contributes to the absolute prevention of the defilement’s future arising. There are therefore as many instances of cessation through deliberation as there are instances of with-outflow entities to be disconnected from.
- (b) Cessation independent of deliberation. This cessation is acquired without specifically applying any effort of understanding, but simply on account of deficiency in the required conditions for a *dharma*’s arising. For example, when the present eye and the mental faculty are focusing on a particular object giving rise to its visual consciousness, it is not possible for any of the five sensory consciousness to arise with regard to any of the other objects (visibles, sounds, etc.) existing in that same moment. There arise accordingly the cessations independent of deliberation of these latter instances of sensory consciousness by virtue of the deficiency in the conditions for their arising. As another example, when one has fully abandoned a certain amount of defilements and attains the spiritual fruition of stream-entry (*srota-āpatti*), causal conditions for rebirth in the unfortunate states of existence (*durgati*) come to be deficient: One acquires the *apratisaṃkhyā-nirodha* of these unfortunate rebirths.

This cessation, too, is a real entity. It is a positive force, and not a mere absence of conditions. It is efficacious in absolutely preventing the possible rearing of the

dharma that has come to be of the nature of nonarising (*anutpatti-dharmaka*).

- (c) The Sarvāstivādins make a clear distinction between conditioned space, which is visible in the openings in windows, doors, cleavages, etc., and the unconditioned space. The conditioned spaces, called the “space element” (*ākāśa-dhātu*), though nonobstructive in nature, are nonetheless obstructed by material things. The unconditioned space, in contrast, is beyond space and time and is characterized by being neither obstructive to, nor obstructed by, any material thing. Its reality is to be comprehended from the fact that there exists the conditioned space which accommodates conditioned things and provides the venues for their activities. This does not mean that space can exercise any activity, but that it serves as a necessary contributing factor – a “dominant condition” (*adhipati-pratyaya*) – through a sequence of conditionality, making possible the fact of cognition of things in space–time. (3, 389a).

It is to be noted that not all canonical Abhidharma texts of the Sarvāstivāda mention space as an unconditioned *dharma*. In the *Abhidharma-mahāvibhāṣā*, we see that some masters, like Dharmatrāta, do not accept space as a real entity. Saṃghabhadra (*ca.* late fourth century C.E.) argues that we can infer its reality from its observable, distinctive function and characteristic (*lakṣaṇa*); and that which possesses a unique function and a unique characteristic is a unique real: Its function is manifested through the fact that it accommodates resistant things; its characteristic – i.e., its observable aspect – is manifested through light (9, 429a–430a. Cf. 6, 496).

The conditioned *dharma*-s, which arise into space–time and their operation therein, are described by two terms: (1) *saṃskṛta* (“compounded”), indicating their aspect of being causally produced by an assemblage of conditions, and (2) *saṃskāra* (“conditioning”), indicating their aspect of being conditioning forces that contribute to the arising and operation of other conditioned *dharma*-s.

The unconditioned *dharma*-s are in complete contrast: Being transcendent to space and time, they are neither causally produced nor do they operate as causes. However, they can serve as “condition qua object” (*ālambana-pratyaya*) inasmuch as they can be apprehended as cognitive objects. The Sarvāstivāda Ābhidharmikas would also concede that in some special sense and in conformity to worldly parlance, it is permissible to speak of the unconditioned *dharma*-s as “efficient causes” (*kāraṇa-hetu*) inasmuch as they do not hinder the arising of other *dharma*-s. Although not causally produced, the cessation through discernment may also be expediently spoken as a “disconnection-fruit” (*visaṃyoga-phala*) inasmuch as it is acquired (*pra-√āp*) through the efficacy of the noble path – even though it is not directly produced by it (2, 91).

The Sautrāntikas deny the realities of all the three types of unconditioned *dharma*-s. But they do not assert that unconditioned things do not exist in any sense – just that they do not exist as metaphysical entities. In particular, *Nirvāṇa* is emphasized as a true spiritual attainment. This, they explain in terms of the doctrine of the transformation of the basis (*āśraya-parivṛtti*) – the spiritual path culminates in bringing about a totally transformed psychophysical basis (*āśraya*) which is completely purified, utterly purged of any latency of defilements:

Nirvāṇa is said to have been attained as a result of the obtaining—by virtue of the counteragent—of a basis which is absolutely opposed to the generation of defilements and rebirth. (2, 93)

Investigation in Terms of Doctrinal Perspectives

Abhidharma also investigates into the nature of *dharma*-s from different doctrinal perspectives. In Vasubandhu’s *Abhidharmakośabhāṣya* (ca. late fourth century C.E.), there are some 22 such perspectives in the first chapter: (1) visible (*sa-nidarśana*), invisible (*anidarśana*); (2) resistant (*sa-pratigha*), nonresistant (*apratigha*); (3) skillful (*kuśāla*), unskillful (*akuśāla*), nondefined

(*avyākṛta*); (4) connected with/pertaining to (*pratisaṃyukta*) sensuality sphere, to fine-materiality sphere, to nonmateriality sphere; (5) with-outflow, outflow-free; (6) with-reasoning (*saṃvitarka*), with-investigation (*saṃvicāra*); (7) with cognitive object (*sa-ālambana*), without cognitive object (*anālambana*); (8) appropriated (*upātta*), nonappropriated (*anupātta*); (9) Great Elements (*bhūta*), derived from Great Elements (*bhautika*); (10) accumulated (*saṃcita*), nonaccumulated (*asaṃcita*); (11) that which cuts (*chinatti*), that which is cut (*chidyate*); (12) that which burns (*dāhaka*), that which is burnt (*dahyate*); (13) that which weighs (*tulayati*), that which can be weighed (*tulya*); (14) the five species: retribution-born (*vipākaja*), accumulative (*aupacayika*), emanational (*naiḥṣyandika*), yoked with a real entity (*dravya-yukta*), momentary (*kṣaṇika*); (15) acquisition (*prāpti/pratilambha*), endowment (*samanvāgama*); (16) external, internal; (17) participative/active (*sabhāga*), nonparticipative/facsimile (*tat-sabhāga*); (18) abandonable through seeing/vision (*darśana-heya*), abandonable through cultivation (*bhāvanā-heya*), not to be abandoned (*aheya*); (19) view (*dṛṣṭi*), not view; (20) consciousness (*viññāna*), object of consciousness (the cognized; *viññeya* – i.e., what elements are cognized by which consciousness); (21) permanent, impermanent; (22) faculties (*indriya*), nonfaculties.

Thus, through such a process of perspectival analysis, the nature of an ultimate real factor in the universe can be articulately determined. For example, a given mental factor is invisible, nonresistant, skillful/unskillful/neutral, nonaccumulative, emanational, momentary, a consciousness or object of consciousness, etc.

Sarvāstivāda Versus Vibhajyavāda

A controversy of fundamental doctrinal importance occurred quite early (probably around third century B.C.) in the northern Abhidharma tradition and came to exert tremendous impact throughout the subsequent development in Buddhist thought. This relates to the question

of the ontological status of *dharma*-s in the three temporal periods.

One camp of thought, described as the “all-exist,” *sarvāstivāda/sarvāstīva*, maintains that *dharma*-s exist in their intrinsic nature through the three periods of time. But temporal distinction is nonetheless possible on account of a *dharma*’s “activity” (*kāritra*), defined as its efficacy to “project its own fruit” – i.e., to serve as the condition for its own rearing in the succeeding moment of its serial continuity. Such an activity, which is neither identical with nor different from the *dharma* itself, is necessarily and uniquely possessed by a present *dharma*: When the *dharma* has not exercised this activity, it is said to be “future”; when it is exercising this activity, it is “present”; when it has exercised this activity, it is “past.” Such is the standpoint of the Sarvāstivāda school and its offshoots (such as the Vātsīputrīya and Sāmmītiya). An important point to bear in mind is that the doctrine of *sarvāstivāda* asserts that “*dharma*-s exist at all times” (*sarvadā astī*), but never that they are permanent (*nīya*) (see above).

The other camp of thought, called the “distinctionist” (*vibhajyavāda*), represented by the Sautrāntikas and others, holds that only the present *dharma*-s are existent. The past and the future are mere concepts (*prajñāpti*) derived on the basis of the present: The “past” is simply “what has been”; the “future” is “what will be.” Some of them, like the Kāśyapīyas, also concede that the *karma*-s that have not given fruit (*adatta-phala*) can be said to be existent (Cf. 6, 117 ff).

Theory of Karma and Causality

The above-mentioned contrasting standpoints have profound implication for the doctrinal interpretations of the Abhidharma schools. For instance, on the question of the preservation of karmic efficacy, the Sarvāstivādins explain that a past *karma* is still existent – it its past “mode of being” (*bhāva*) – and is still causally efficacious, albeit devoid of “activity.” It is

therefore capable of yielding a fruit at some point in the future. In fact, a nonexistent cannot be causally efficacious.

The Sautrāntikas, on the other hand, must explain everything in terms of the single present moment. In this connection, they developed the theory of the seed (*bīja*): The momentary volition (*cetanā*) qua *karma* projects into the mental serial continuity of the person a specific efficacy which is continuously transmitted from moment to moment. At a distinctive point of this serial continuity which has been undergoing a process of transformation (*saṃtati-pariṇāma-viśeṣa*) in terms of the progressive maturation of the karmic efficacy, when the required assemblage of conditions is obtained, the corresponding fruit is generated. This efficacy in the serial continuity is called the “seed,” which is neither identical with nor different from the serial continuity.

Another important difference among the Abhidharma schools relate to their theory of causality. All Abhidharma schools accept that *dharma*-s are momentary (*kṣaṇika*). The Sāmmītiya (like the Theravāda) is an exception, holding that material things last relatively longer than the momentary mental factors. However, these various schools differ with regard to their understanding of the causal process. The Sarvāstivādins and others uphold the theory of simultaneous causality (*sahabhū-hetu*): Cause and effect can exist simultaneously. In contrast, the Sautrāntikas and others maintain that the causal process is strictly sequential: A cause necessarily precedes an effect. As a result, the two schools developed contrasting theories of perception. For the Sarvāstivāda, a sensory object is directly perceived, since the sensory faculty, the external object, and the resulting sensory consciousness all arise in the same moment. For the Sautrāntikas, all perceptions are indirect (*apratyakṣa*) and representational. In the first moment, the sensory faculty and object exist; the sensory consciousness then arises in the next moment: As the object arises only to cease, it leaves behind an imprint or exact

resemblance (*ākāra*) of itself, which becomes the cognitive object (*ālambana*) that generates the corresponding knowledge of it in the next moment. Thus, external reality is never known directly; its knowledge is necessarily derived from our mental content. This theory came to be known as the “theory of the inferability of the external object” (*bāhyārtha-anumeyavāda*) (Cf. 4, 136 ff).

Introduction

The capacity to generate movements is a characterizing aspect of animals' behavior. Some movements are rigidly determined by external or internal stimuli. They are called *reflexes*. Others are manifestations of a centrally generated intention to act. They are called *voluntary movements*. The way in which intention to act is generated is irrelevant for the notion of voluntary movement. It may result from bodily needs such as hunger or thirst, or from higher-order deliberations based on one's own beliefs and desires. What counts for voluntary movements is that the individual has a goal and that this goal determines movements leading to its achievement.

Being endowed with the capacity to generate movements, animals move in their environment looking for objects or situations that may satisfy their immediate or future needs. When they find an appropriate stimulus they may interact with it. Unlike for reflexes, however, in voluntary behavior stimuli do not determine the response, they only *set the occasion* for it. According to their needs, animals may respond to the same stimulus in different ways. They may approach it, avoid it, or ignore it.

Action Control, Fig. 1 Lateral view of macaque monkey cerebral cortex showing frontal and parietal areas. The intraparietal sulcus is opened to show areas located in its medial and lateral banks. Motor areas are indicated with F and Arabic numbers; parietal areas are indicated with P and progressive letters. For nomenclature and definition see Rizzolatti and Luppino (2001). Abbreviations: AIP

anterior intraparietal area, AI inferior arcuate sulcus, AS superior arcuate sulcus, C central sulcus, Cg cingulate sulcus, L lateral fissure, LIP lateral intraparietal area, Lu lunette sulcus, MIP medial intraparietal area, Opt occipito-parieto-temporal area, P principal sulcus, ST superior temporal sulcus, VIP ventral intraparietal area

The region centrally involved in the genesis of voluntary movements is the posterior part of the frontal lobe. Classically, this region was subdivided into two areas: the primary motor cortex, located on the cortical convexity and the supplementary motor area located on the medial aspect of the hemispheres. Modern data showed that this region is actually formed by a mosaic of different areas with specific functions and connectivity (Fig. 1). These premotor areas code different types of motor behavior among which are hand grasping, arm reaching, mouth movements, and different types of eye movements (Rizzolatti and Luppino 2001).

The frontal motor areas receive inputs from the anterior part of the frontal lobe that plays a crucial role in the control of overt behavior, setting when a voluntary action may or may not be executed, and from parietal lobe. Classically, this lobe was thought of as an association area combining all sorts of sensory stimuli mostly for space perception. Modern research showed that the basic organization of the parietal lobe is in terms of a motor representation of body parts (Hyvärinen 1982). On the top of this basic motor organization, an integration of motor information with sensory

inputs gives origin, in higher primates, to cognitive capacities such as space perception and comprehension of intentions of others (Rizzolatti et al. 2001).

In this entry we describe the neural basis of a specific voluntary behavior: that enables primates to interact with objects. Our aim, by using this behavior, is to outline some general principles of action organization.

The Importance of the Hand

Unlike most mammals, primates have a prehensile hand. This evolutionary achievement tremendously enriched their motor capacities and had profound consequences on the development of cognitive capacities. As the German philosopher Friedrich Engels wrote in 1882: “Man alone has succeeded in impressing his stamp on nature. He has accomplished this primarily and essentially by means of the hand. But step by step with the development of the hand went that of the brain” (Friedrich Engels 1882).

The evolution of the hand’s prehensile abilities radically changed the way in which primates relate

themselves to the external world. For primates, humans in particular, objects are not only something on which to jump or avoid, but things that can be *used*. This required the evolution of new cortical circuits that enable the transformation of objects into motor acts having different purposes.

The Organization of Grasping

The behavioral analysis of reaching to grasp movements showed that an individual facing an object performs two main separate, although interacting, series of computations in order to get possession of it (Jeannerod 1988; Fagg and Arbib 1998). One is the transformation of the spatial position of the object into the appropriate reaching movement; the second is the transformation of object intrinsic properties (e.g., shape and size) into an appropriate hand shaping. The notion that operations underlying reaching and grasping require parallel processing has been fully confirmed by neurophysiological studies (Jeannerod et al. 1995). Here, we describe the motor act of grasping a paradigmatic example of action organization.

The cortical circuit mostly involved in the organization of grasping is formed by a parietal area (area AIP) and a premotor area (area F5) (see Fig. 1). Single neurons were recorded from area AIP in behaving monkeys trained to grasp different types of objects. It was found that the most neurons fired during grasping performed with a specific grip. Furthermore, many AIP neurons, with or without motor properties, responded to object presentation. Most interestingly, neurons that discharged selectively during grasping of a specific object also discharged during the observation of that object. This finding suggests that AIP neurons are involved in the transformation of seen objects into the representations of how to grasp them (Rizzolatti and Luppino 2001; Jeannerod et al. 1995).

A similar experiment was performed on the premotor area F5 where a motor representation of hand is located. The results showed that area F5 contains neurons that discharge in association with different types of hand motor acts (e.g., grasping, holding, manipulating). Some hand-related neurons

were active regardless of how the object was grasped. Most, however, discharged only when the monkey grasped objects using specific types of grips. As in AIP, a considerable portion of F5 neurons also discharged when the monkey simply observed an object. The visual and motor responses of majority of these neurons (called “canonical” F5 neurons) were congruent one with another (Rizzolatti and Luppino 2001; Jeannerod et al. 1995) (Fig. 2).

What is the meaning of this coupled visual and motor discharge? The most accepted interpretation is that the object presentation determines the transformation of the object visual properties into a *potential motor act*. Every time an appropriate object is presented, AIP and canonical F5 neurons code a potential motor act toward it. The potential motor act may be executed or not (Jeannerod et al. 1995).

A Model of How Objects Are Transformed into Potential Motor Acts

A fundamental property of neurons of AIP and F5 is that they respond to the presentation of three-dimensional objects. The functional meaning of these responses could be understood considering the notion of “affordance” introduced by James J. Gibson (1979). According to Gibson, the observation of an object entails an immediate and automatic selection of those of its properties that allow one to interact with it. The affordances are not the visual aspects of the object, but the *pragmatic opportunities* that the object offers to the observer.

Visually responding AIP neurons represent the stage in this processing in which, after the extensive elaboration of object visual properties in the extrastriate visual areas, affordances became the neuron triggering features. This information is then sent to AIP and F5 visuomotor neurons, which code potential motor acts. Because of the congruence between AIP and F5 neuron responses elicited by a specific object characteristic (i.e., by its affordance) and the motor act they control, a given object affordance is transformed into the appropriate potential motor act. Objects become motor acts.

Action Control, Fig. 2 (continued)

The Importance of Potential Motor Acts for Increasing the Individuals' Freedom and Understanding the Actions of Others

An extremely important characteristic of F5 canonical neurons is that they discharge both when the monkey performs a motor act like grasping *and* when an appropriate visual stimulus is presented. Note that, in both cases, the experimenter records the neurons' output, that is, the message that the neuron sends to other neural centers. Because of this, the experimenter knows the meaning of neuron discharge even when there is no overt behavior. If the overt motor act, associated with neuron discharge, is grasping, the firing of that neuron in the absence of an overt movement also means grasping. However, because there is no motor response, the grasping in this case is a *potential* motor act and not an overt response.

The presence of potential motor acts has two important functional consequences. First, this mechanism enables the individuals to decide whether or not to respond to a given stimulus. The vision of a graspable object does not necessarily lead to grasping. The object may be acted upon, the action may be delayed, thus choosing the moment most appropriate for performing it, or may be not emitted at all.

Second, recent data showed that, besides canonical F5 neurons, there is another set of visuomotor neurons in F5 that respond both when the individual makes a given motor act *and* when it observes another individual doing the same act (Fig. 3). For these neurons, called "mirror neurons" the effective visual stimulus is not the object affordances as for the canonical neurons, but the observation of

a motor act done by another individual. If one considers that the same motor pattern is evoked, *internally*, when the individual intends to do an action, and *in response* to the observation of the same action done by another individual, it is very plausible that that the potential motor act evoked by observation of others gives meaning to the observed action (Rizzolatti and Sinigaglia 2007). The mirror mechanism is considered one of the ways in which individuals understand others and the only one that gives an experiential knowledge of what the others are doing.

Conclusions

Historically, the motor system has been considered as a mere executor of commands coming from higher-order association areas. A common view was that the motor system exist "to *translate* thought, sensation, and emotion into movement" (Mountcastle et al. 1975). According to this view, all the more "intelligent" processes occur before its activation. The example we described of how the control of grasping is achieved and, in particular, the existence of potential motor acts indicates the close relation between the motor system and higher cognitive capacities. Even more telling is the presence in the cortical motor system of neurons that are involved in understanding motor acts done by others. The modern view of the motor cortex is that of a system intimately linked to perception and cognitive functions and, according to some, the backbone on which conscious perception evolutionary originated.

Action Control, Fig. 2 Example of an F5 canonical neuron. The *upper part* of the figure (object grasping) shows the neuron's activity during observation and grasping of different objects. The monkey was seated in front of a box, which housed six different objects. Objects were presented one at a time in a central position in random order. Rasters and histograms are aligned with the key press (the moment when the object became visible). In the ring grasping panel, the second peak of discharge corresponds to the activity related to the grasping movement.

The *lower part* of the figure (*left*) shows the activity of the same neuron during object fixation (only the responses to the *ring* are shown in the figure). Rasters and histograms are aligned with the key press. The *lower part* of the figure (*right*) shows the activity of the same neuron during fixation of a spot of light. In this condition, the task was the same as in the object fixation condition, but carried out in the dark. No object was visible and the monkey simply was required to fixate the spot of light

Action Control, Fig. 3 Example of the visual and motor responses of an F5 mirror neuron. The behavioral situations during which the neural activity was recorded are schematically illustrated near the rasters. (a) A tray with a piece of food placed was presented to a monkey that grasped the food and ate it. The monkey from which neuron was recorded observed the first monkey.

(b) A piece of food on a tray shown to the monkey, the experimenter grasped it. (c) Neuron activity recorded when the monkey grasped the food. Clear responses of the neuron were present both during grasping and grasping observation. Abscissae: time. Ordinates: spikes/bin. Bin width: 20 ms

Description

Aesthetics is a branch of philosophy that is concerned with two general domains: the philosophy of art and what may be considered the philosophy of aesthetic experiences, especially the experience of beauty and ugliness. In the philosophy of art, philosophers in aesthetics have developed different definitions or analyses of what makes an object or event a work of art, different accounts of the meaning of art, its value,

and the relationship of art to other domains. How does the art world intersect with the world of culture as a whole, the world of politics, commerce, religion, and so on? When the term “aesthetic” is used to refer to experience, it is customarily used to pick out emotive features, as in the experience of the austere desert, the moody valley, the sanguine brook, the sublime mountain, and so on. Such motive features seem to mark the object, as we experience it. Thus, Beethoven’s ninth symphony may be experienced as itself joyful, and not merely thought to be joyful because it makes listeners and performers feel joy. The precise nature of such experiences is (as in most topics in philosophy) under debate.

The term “aesthetics” was introduced in the late nineteenth century and the field (as just described) took shape gradually in the twentieth century, but reflection on beauty and art may be traced back to Plato. Arguably, Plato was the first philosopher to develop a substantial position in aesthetics. He held that there was an ideal form of beauty and that the beautiful things we observe are beautiful because they participate in this ideal form. He treated matters of beauty as objectively real (not as a matter of taste), and he thought that works of art must involve “techne” or a disciplined practice. In his dialogues, the *Ion* and the *Republic*, Plato advanced the thesis that Homeric poetry is not a proper art form. Aristotle was the next great contributor to what we would today call aesthetics. He defended Homeric poetry and theater and other artistic practices as proper disciplines while also serving an overall good in terms of the moral formation and enrichment of citizens.

David Hume in the eighteenth century was one of the most prominent of those in the history of ideas in the west to propose that beauty is in the eye of the beholder. Even so, he thought that there were standards that were better or worse when it comes to assessing beauty.

Today, the field of aesthetics is diverse. There are contemporary versions of aesthetic theories that are Platonic, Aristotelian, Humean, and a plethora of different methods and topics. Contemporary philosophers disagree on the normative nature of beauty.

Self-Identification

Science

There have been scientific accounts of the aesthetic experience. Evolutionary biologists have debated about the role of beauty in mate selection, for example, and this was a matter that very much engaged Charles Darwin and the co-founder of the theory of evolution, Alfred Russel Wallace. It has also been argued that the practice of science itself involves aesthetic standards, for example the appeal to elegance, simplicity, coherence, and the like have been thought of as aesthetic properties.

Religion

The discipline of aesthetics has involved the philosophical exploration of the religious implications of art, and there have been many philosophers who have engaged in aesthetics with an eye on considering the cognitive value of religious experience. This may be seen clearly in the works of Coleridge, the British romantic poet and Platonist. There has been recent work that has also studied the aesthetics of religious versus secular views of the world. The most recent example is *The Image in Mind: Imagination, theism, and naturalism* by Charles Taliaferro and Jil Evans.

Characteristics

Aesthetics is distinguished from other branches of philosophy by its subject matter. No other discipline is devoted explicitly to reflecting on the nature and value of beauty or of artworks, though one might do so in the context of axiology (the study of values) or ethics (when assessing the comparative worth of beauty and, say, principles of justice). Aesthetics is also a domain that takes up topics of great interest which are not otherwise typically covered by other subdisciplines. So, in aesthetics one investigates the nature of imagination and creativity. While imagination may come up in the course of epistemology or even metaphysics (Can one imagine other possible worlds?), imagination and creativity (as topics) are very much at home in aesthetics.

Relevance to Science and Religion

There has been recent interest in what might be called the aesthetics of science and religion, as noted earlier. In *The Image in Mind*, Taliaferro and Evans juxtapose the aesthetic dimensions of naturalism and theism. Many of the proponents of atheism, sometimes called “the new atheists,” may be read as offering an aesthetic critique of religion, sometimes in the name of science (Richard Dawkins seems to fit this description). And defenders of religious beliefs and practice offer a counterpoint, arguing that there is an ugly side to “new atheism.”

Some philosophers in aesthetics who are in the general, Platonic tradition (Douglas Hedley, Mark Wynn, Anthony O’Hear) tend to argue against what may be called “scientism,” the view that the sciences (especially the natural sciences) can offer a sufficient description and explanation of our life and values, including aesthetic values.

Sources of Authority

Categories are varied. Because aesthetics involves two domains (art and experience, in general) that are overlapping, the sources will vary depending on the way aesthetics is carried out. If, for example, one is concerned with the philosophy of art, then a chief source of material for reflection will be artworks themselves. What kinds of things or events have been considered or are being considered works of art? Presumably, a philosophical account of what it is to be a work of art needs to be responsible to the history and culture of art making. Questions about the meaning of works of art would presumably rely upon the discipline of history. One needs reasonable, reliable accounts, of how persons have treated the meaning of works of art over time in order to construct a philosophy of meaning.

In terms of the philosophy of beauty, philosophers have used a balance of reason and experience. One may refine this more with reference to phenomenology (the study of experiences, such as the experience of what we take to be beautiful)

and conceptual analysis (considering the concept of beauty, artwork, and so on).

Aesthetics as a practice often involves thought experiments. So, the way a philosophy of art may be tested is in terms of whether the philosophy can satisfy not just all actual works of art, but of imagined artwork as well.

There is also what is sometimes called “the test of time,” which is sometimes used in the assessment of works of art, that can also be applied to aesthetics itself as a discipline. The extent to which a philosophy of art or imagination can stand the test of time (stand up to counter-examples and arguments) it may be considered more sound than a philosophy that has not been so tested.

Ethical Principles

The ethical principles of aesthetics are those that pertain to academic publication and discourse generally. There is, however, interest in aesthetic accounts of ethical principles. Could it be that our senses or judgments of right and wrong are rooted in our aesthetic attraction to or revulsion of certain things? While an affirmative answer to such a question was a hallmark of positivism in the twentieth century and its rejection of ethics as a cognitive discipline, one can answer the question affirmatively and adopt a position of moral realism. In the nineteenth century, Brentano contended that ethical principles could be analyzed in terms of what persons should (correctly) love or not love.

Aesthetic work on the value of artworks also concerns itself with moral principles. There is currently significant debate about whether an artwork that promotes something unethical is thereby deficient as a work of art.

Key Values

Among the key values in aesthetics is its engagement with the world of art (historically and today) within and across cultures. Insofar as aesthetics also involves the philosophy of beauty, it invites

reflection on what aesthetic values are specific to a culture, and which values are cross-cultural. In terms of methodology and marks of excellence in the works of aesthetics: Key values include conceptual clarity, comprehensiveness, openness to counterarguments, historical soundness, scope (not employing too narrow a scope of art or artists), and beauty. A philosophy of beauty can itself be beautiful.

Conceptualization

Nature/World

Aesthetics is interested in the concept of nature and such questions as: Is the natural world beautiful? sublime? In environmental aesthetics, there is a concern to articulate the differences between an aesthetic appreciation of the environment when this is informed by the natural sciences or not. There is no single concept of “nature” accepted by all working in aesthetics. The concept of a “world” does have a use among some philosophers of art. Some artworks may be thought of as interacting with the world, for example a sculptural figure in a palace. But some works of art, like a novel or painting or play, may be thought of as constituting a world. J.R.R. Tolkien’s *The Lord of the Rings*, for example, may be thought of as a world in which readers enter.

Human Being

There is no one theory of human beings put forth by the field of aesthetics, except that there is probably a common assumption by almost all in the field that aesthetics (as this concerns works of art and beauty/aesthetic experiences) is a vital element in human life.

Life and Death

Philosophers working in the field of aesthetics do not share a common view of life and death, but they have given attention to what may be called the aesthetics of life and death. Some Christians in aesthetics treat death as something ugly (it is perhaps necessary to pass through, but not something that is itself fitting and possibly beautiful),

whereas secular naturalists tend to think that death is natural and not something ugly, in the case of someone who lives “a natural life span.”

Reality

There is some concern in aesthetics over the extent to which beauty and ugliness are objective properties of reality itself. Are some things in reality supposed to be the objects of pleasure or revulsion? Also, to what extent is reality, as revealed in human experience in affective terms (the tree looks sad, the sea feels angry, the mountain appears majestic), truly real or simply a reflection of our psychological attitudes?

Knowledge

In aesthetics, there is concern for (a) the extent to which we may know truth claims about beauty or works of art and (b) how much must be known about X (whatever) to know its value, meaning, or beauty or ugliness. So, some in aesthetics think that if you are assessing the meaning of a novel or poem, it is absolutely irrelevant what the novelist or poet was intending. On this view, one need not know anything of the biography of the artist. A growing number of philosophers disagree (Gary Iseminger).

Truth

Philosophers working in aesthetics have different views about the relationship of works of art to truth. Some think that a mark of excellence of a work of art is (partly) determined by the extent to which the work of art sheds light on the truth of its subject matter. A feminist (as well as many who do not self-identify as feminists) may object to a work of art because of its advancing a corrupt, sexist understanding of what it is to be female.

Perception

In aesthetics, philosophers have been concerned with the extent to which our perception is suffused with affective properties (properties with aesthetic content) and the implications of such properties. Is the fact (if it is one) that most human beings find certain acts ugly/revolting evidence that in fact such acts are (objectively) bad and deserve our disapprobation?

Time

Time is philosophically interesting in aesthetics for different reasons. Here are six matters:

First, there is “the test of time” that is sometimes used in assessing the value of a work of art.

The fact that Shakespeare’s work has been appreciatively embraced as great over many centuries may be taken as one reason to think it deserves praise.

Second, time seems to be part of certain works of art such as music.

Third, some philosophers in aesthetics believe that the meaning of an artwork can vary over time. Hamlet might have had one meaning when first performed (e.g., an embodiment of Protestant anxiety) and another at a later date (when performed in London during the Second World War, it may have embodied the spirit of the nation).

Fourth, some philosophers have contended that in a photograph, you actually see the past.

Fifth, there is a philosophy of ruins. For some, a ruin of an ancient civilization may be a sign of a past golden age, whereas for others it may be valued as a humble realization of the effects of time.

Sixth, how should artworks be cared for over time. Should we seek to preserve the way they looked when first made? Or should they be allowed to decay over time?

Consciousness

Some philosophers have considered the aesthetics of different accounts of the emergence of consciousness. See *The Image in Mind*.

Rationality/Reason

In the philosophy of art, rationality and reason have sometimes been seen in contrast to passion and the imagination (as in the Romantic tradition). One interesting account of reason in aesthetics has involved the invocation of ideal aesthetic observation. According to some, the ideal point of view to assess the aesthetic properties of an object or event would be to have almost limitless experiential access to the object or event, to be impartial, to know all of its history, and so on.

Mystery

Some philosophers treat aesthetic properties, as well as beauty, as basic, and not further explainable. Iris Murdoch may be a good case in point. She thinks that beauty is real, and it is not reducible to any sub-category such as ethics or psychological appetites.

Relevant Themes

Beauty and Ugliness: To what extent is a scientific view of the world beautiful or ugly? To what extent is a religious view of the world beautiful or ugly? These are questions explored at length in the book *The Image in Mind: Imagination, theism, and naturalism*.

Religious and Aesthetic Experience: David Brown has argued that our aesthetic experiences of the world are an important resource for theology.

Affective/Emotional Computing

Sidney D'Mello

Departments of Psychology and Computer Science, University of Notre Dame, Notre Dame, IN, USA

Related Terms

[Computer science](#)

Description

The field of affective computing aspires to narrow the communicative gap between the highly expressive human and the socially challenged computer by developing computer interfaces that recognize and respond to the affective states (or emotions, e.g., frustration, surprise) of the user. Stemming from Picard's influential book (Picard 1997), affective computing is motivated by the assumption that computer systems that are able to recognize and respond to users' affective states (in addition to their cognitive states) will provide a more effective, meaningful, and naturalistic interaction experience. This assumption is grounded in contemporary psychological and neuroscience theories that claim that cognition and emotion are inextricably bound as emotion influences cognitive processes such as perception, memory, deliberation, problem-solving, planning, and action (Barrett et al. 2007; Damasio 2003; Lazarus 1991).

One major goal of the field is to develop computer systems with a degree of *emotional intelligence* (Goleman 1995). These affect-sensitive interfaces automatically detect users' affective states, respond in an affect-sensitive fashion, and even synthesize affect. *Affect detection* involves the development of sensors and computational algorithms to monitor and extract the affective content from users' physiological, behavioral, and verbal signals. Examples of physiological channels include *electrodermal response* and *electrocardiography*, while *facial expressions*, *speech contours*, *gross body movements*, posture, and gestures are the widely used behavioral channels to detect affect. Affect can also be inferred from a textual analysis of a users' utterance by analyzing the linguistic, syntactical, and semantic content of the utterance.

Once a user's affective state is detected, an affect-sensitive interface needs to respond to that state much like a human would. These affectively modulated responses should be tightly coupled to the environment supporting the interaction (i.e., the context of the interaction). For example, a computer tutor that detects that a human student is frustrated might make an empathetic remark (to acknowledge the student's frustration) and offer a hint (to presumably alleviate the student's frustration). In contrast, an affect-sensitive e-mail client that senses that a user is frustrated might suggest postponing the transmission of an angry e-mail (sensed from a textual analysis of the message).

In addition to detecting and responding to users' affective states, affect-sensitive interfaces with *embodied conversational agents* may also synthesize affect via facial expressions, inflections of speech, and body language. For example, an embodied conversational agent simulating a human tutor might synthesize encouragement by leaning forward, smiling, and increasing the pitch of its voice.

Recent advances in affective computing involve the development of nonintrusive physiological and bodily sensors along with computational systems that automatically detect affect with moderate accuracy in real-world environments (Calvo and D'Mello 2010; Zeng et al. 2009). While most of the

earlier systems focused on physiological measures, facial expressions, and paralinguistic features of speech, affect detectors that combine these classical channels with more novel sensors are coming online.

Although virtually any human-computer interface can be transformed into an affect-sensitive interface, some of the recent applications have involved affect-sensitive *intelligent tutoring systems* (D'Mello et al. 2007), affect-sensitive virtual avatars for online communication, and systems that facilitate emotional communication for individuals diagnosed with *autism spectrum disorder* (Madsen et al. 2008) (see <http://emotion-research.net/> for more information).

In addition to building functional affect-sensitive systems to assist users, the field is also devoted to understanding how humans experience, express, and regulate their emotions. Rigorous empirical investigations and computational modeling of users' affective experiences guide this endeavor. In this fashion, affective computing is a truly interdisciplinary field encompassing computer science, artificial intelligence, human-computer interaction, engineering, psychology, cognitive science, and artifact design.

Self-identification

Science

Affective computing self-identifies as a science. Before building computational systems to respond to affect, one must first understand how humans experience, express, and regulate their affective states. Hence, researchers in the field of affective computing conduct empirical investigations into the nature of human emotions via observations and experiments. In addition to empirical research, researchers also routinely build computational models of important affective phenomenon (Conati and Maclaren 2009). Insights gleaned from the empirical studies on human emotions and the subsequent computational modeling are leveraged towards engineering functional systems that address practical problems related to affect-sensitivity in different human-computer interaction contexts.

Characteristics

Affective computing can be distinguished from broader fields such as human-computer interaction, human factors, ergonomics, artificial intelligence, computer science, and cognitive science by its focus on affective states (in conjunction with cognitive and motivational states) and its goal of building functional affect-sensitive systems rather than simply studying human emotions.

Relevance to Science and Religion

Affective computing researchers are currently more interested in practical problems related to detecting and responding to affective states. They are less concerned with the issues pertaining to “science and religion.”

Sources of Authority

Affective computing has a science and an engineering side. Sources of authority on the scientific front are peer-reviewed publications that focus on empirical research on how humans experience and express affect. Falsifiable theories, empirical data, and replication of experiments are authoritative for affective computing researchers. On the engineering side, systems that work and can be deployed in real-world contexts as well as peer-reviewed publications describing and evaluating these systems are sources of authority.

Ethical Principles

Full disclosure of methods used to study human affect so that empirical research can be replicated, and honest descriptions and evaluations that highlight both the strengths and weaknesses of affect-sensitive interfaces are important ethical principles. Affect-sensitive systems attempt to diagnose and respond to human emotions; hence, nonmaleficence is also an important ethical principle.

Key Values

Building better computer systems to assist humans is a key value. Honesty in all research activities, intellectual curiosity, and a willingness to undertake challenging problems where success is sometimes indeterminate and fuzzy are key scientific values of affective computing.

Conceptualization

Affective computing does not explicitly conceptualize these terms.

Relevant Themes

There are no additional issues relevant to science and religion engagement.

Affordances

Harry Heft

Department of Psychology, Denison University,
Granville, OH, USA

The perceived functional significance of environmental features taken relative to an individual. For example, a surface at approximately knee height to an individual is perceived as affording sitting-on. To perceive an object's affordances is to perceive its meaning relative to the actions of the self/another individual. Affordances point to a domain of values/properties that is neither "in" the environment, considered apart from an individual, nor "in" the mind, considered apart from the environment, but rather are relational properties of an environment-organism system. Formulated by James Gibson in his ecological approach to perception-action.

[African indigenous counselling](#); [African traditional counselling](#)

Description

African psychotherapy, also referred to as "African indigenous counseling" or "African traditional counseling," can be defined as a subdiscipline within the currently more inclusive field of psychotherapy in Africa (Madu et al. 1996), devoted to the study of the psychological healing systems indigenous to the traditional communities of Africa (Nwoye 2010). Until recently, its initial preoccupation was the systematic study of the patterned ways and rituals, theories, and techniques, invented in indigenous African communities for addressing the psychological needs and problems of living in the African world. This definition implies that there are many dimensions to the meaning of the term African psychotherapy. One of these is that it has both a precolonial and postcolonial reference. In its precolonial emphasis, it is concerned with the task of understanding the various healing practices, processes, and rituals set up in indigenous African communities for assisting clients in traumatized circumstances and in making big life decisions. In its postcolonial concerns, it is

interested in helping modern African clients to regain belief in themselves and to find their way successfully through the complicated and difficult contemporary African environments.

Another dimension of its meaning that is not often well represented in the literature is that African psychotherapy is also concerned with achieving an understanding of the African worldview as a background for gaining a deeper appreciation of the African's perception of his or her world and his or her place within it. The African worldview implies unpredictable life events influencing people's destiny in the world. In this perspective, human beings have limited agency rather than complete control of what happens to them in this world. This angle of its preoccupation is important. It is from studying such a worldview that the practicing counselors in modern Africa would be able to discover important assumptions that contemporary African clients make regarding who to blame or not to blame for the sources and meanings of their various frustrations and difficulties.

In terms of the beneficiaries of its interventions, one can see that, broadly speaking, people judged in need of counseling in traditional and modern Africa are not restricted to those with important and difficult decisions to make in life. This is because in traditional African psychotherapy, even those with impatient and impulsive temperamental dispositions are equally seen as fitting cases for counseling. Through counseling, the elders and the relatives enjoin such people to reconsider their ways. In addition, people about to get married and those in grief and loss are equally considered as fitting cases for counseling in indigenous and modern Africa. In the context of grief work in Africa, for instance, the practice of counseling is often not confined to the idea of a psychological service which one individual gives to another individual in need of emotional support and care, but indeed extends to the important healing role of the community in bringing succor to one of their members in distress (Nwoye 2005a).

However, in whatever way it is delivered, whether for and by an individual or a group, the essential point is that in the actual practice of African psychotherapy, *the art of conversation* in which healing is effected through interpersonal meeting or the heart-to-heart dialogue between persons is valued very highly. Hence, the major techniques of African psychotherapy include oral dialogue; effective use of proverbs that inspire the need for inner recollections/reflections; didactic fixed expressions; and insight-promoting myths, stories, and wise sayings.

In terms of recent developments in African psychotherapy, one can say that, presently, some African counseling practitioners operate as bridge builders after receiving training in both the theories and techniques of the Western and the African indigenous healing systems and use their discretion to determine when each approach should be drawn upon and synthesized to form a more critical mass for successfully confronting the problem presented by contemporary African client/s. And there exist some important literatures that give an account of such new developments in the context of psychological therapies within the modern African continent (Madu et al. 1996; Makinde 1978; Moodley and West 2005; Nwoye 2010).

Self-identification

Science

African psychotherapy identifies itself as a science and as an art. In their research engagements, African psychotherapists are guided by the procedures emphasized in the research methods of the social science disciplines particularly Western psychology from which most of its practitioners have received training. However, in addition to operating in line with established scientific principles in its research endeavors and theoretical assumptions, from the point of view of their practice, African psychotherapists operate as artists, humanists, or people-makers, placing particular premium on the role of

interpersonal dialogues and the miraculous power of words in bringing healing to people in distress. Hence, one can say that African psychotherapy is essentially humanistic in emphasis with the goal of rational decision-making, cognitive restructuring, emotional healing, and problem dissolution as its major targets of intervention. In this way, African psychotherapy can be described as a discipline that promotes the processes of human care which according to Watson “consists of transpersonal human to human attempts to protect, enhance, and preserve humanity by helping a person to find meaning in illness, suffering, pain, and existence; to help another to gain self-knowledge, control, and self-healing wherein a sense of inner harmony is restored regardless of the external circumstances” (Watson 1985).

Religion

African psychotherapy does not self-identify as a religion. However, it is influenced in its practice models and rituals of action by the African worldview which is essentially religious in nature. The term African worldview is used in this context to refer to the African’s view of and approach to his or her world. Such a worldview is said to imply a religious perspective, encompassing a belief that the world is made up of two interdependent realms: the visible and the invisible or the material and the spiritual planes. Under this platform, the invisible realm is believed to be peopled by supernatural agencies, some of which are benevolent, while others are malevolent to humans in the world. The visible realm on the other hand is believed to be the abode of human beings and other material forms of existence, some of which are good, while others are evil in their direct or indirect effects on other lives in the world. Based on this understanding, African psychotherapists agree that the average African holds a precarious view of the universe (Kalu 1978).

In addition, one of the major reasons for the study of African psychotherapy is to prevent the extinction of and to recover and preserve the valuable ways and rituals of psychological healing systems indigenous to Africa. In this

context, it operates in the same line and spirit as those like African history, African religion, African literature, African music, and African archaeology, all of which support the call by African writers and leaders of thought such as Chinua Achebe and Ngugi wa Thiong’o for the need, which modern Africans have, to reassert their cultural heritage in all the various departments of life. The aim is not only to prove to non-Africans that we have something of value to share with the rest of the world in the area of theory and practice of psychological healing but also to get to understand the African worldview that controls the way the African client interprets his or her world, the sources of his or her problems and what she or he needs to do to resolve them. It is, of course, believed that when the non-African audience explores and understands the content and message of the African worldview, a better understanding between Africans and their foreign partners can ensue.

Characteristics

One unique element in African psychotherapy lies in the great respect it accords to understanding and working in line with the spiritual view of the people (Nwoye 2002). Another unique aspect of African psychotherapy in which it differs very much from the general philosophy of practice in Western psychotherapy (where professionals stay in their clinics to be sought out by needy clients) is that often in traditional Africa, counseling is not given at the formal request of the counselee. Rather, members of the community may often see the need to give counseling and guidance to their member(s) in need, particularly those traumatized by negative experiences. In that case, the intended beneficiary may not seek out for such counseling service. The people opt to visit him or her with their service/care, acting in the conviction that that is what they ought to do to assist their member(s) or friend(s) in need. In this way, the approach is not understood as a meddling but rather as a means of helping to lighten the burden faced by one of their own.

Relevance to Science and Religion

African psychotherapists do not participate in the scholarly debates within the area of “science and religion.” But in its research and practice, it recognizes and respects the spiritual view of the people and believes in the power of religion to fight against the crises of despair and demoralization in people overcome by the challenges of living in the difficult contemporary African world in which the ravages of war, poverty, and disease confront millions of people with enormous pain and distress.

In addition, the creative response of many trained African psychotherapists in modern Africa, particularly members of the clergy (who combine their African orientation with professional training in spiritual counseling), is to direct some of their skilled assistance toward the development and management of hope-healing communities intended to inspire and encourage the people in their difficult circumstances. In the majority of cases, the prayer sessions/services organized by these communities take place in an open-air theater platform to accommodate the mammoth crowd who come from far and near to attend the hope-healing sessions/services. Thus, some healing sessions/services of the most popular of these ministries have very close resemblance with the atmosphere of healing in ► [agoral gathering](#), as reported by Biela and Tobacyk (1987). Such communities serve as a place of spiritual renewal for those who participate in them. The participants use them as a place where they can go to be taught by God and to report their problems to Him. Presently, there are many such hope-healing communities found scattered in all the corners of the continent. The leadership of these communities typically goes along denominational lines. This is why it is amazing to see the enormous similarity of pattern of organization and theme emphases in the services and sessions of the six communities studied and reported by this present author in the article from which some of the data quoted above are drawn (Nwoye 2002).

The above indications imply that although African psychotherapists may not have

participated directly in the current scholarly debates on the interconnections between science and religion, some organize some healing practices that respond to the religious needs and views of the people.

Sources of Authority

There are multiple sources of authority for African psychotherapy. Some of these derive from results of continuing in-depth study of the variety of the psychological healing systems indigenous to Africa. Others come from results of cultural studies on the wealth of African ways and wisdom such as embedded in African proverbs, didactic myths, and figures of speech propagated in the works and writings of illustrious African novelists like Chinua Achebe, Wole Soyinka, Elechi Amadi, Sam Aluko, Flora Nwapa, Mariama Ba, Tsitsi Dangaremba, Buchi Emecheta, etc. From such sources as these, the needs, aspirations, beliefs, and worldview of indigenous African men and women are mined. And these help the African psychotherapists in understanding the stories of pain and despair of modern African clients. Current practices in African psychotherapy are also influenced by the theories and writings of important Western authorities in the field of mainstream psychology and counseling, such as those by Sigmund Freud, Carl Rogers, Carl Gustav Jung, Alfred Adler, Fritz Perls, Albert Ellis, and Aaron T. Beck. Modern African psychotherapists are equally influenced in their family therapy practice not only by the views and perspectives of Western authorities on the matter (e.g., Salvador Minuchin and Boszormenyi-Nagy) but also by the values and approaches of African indigenous marriage and family therapy systems.

In African psychotherapy, the notion of authority does not derive merely from the newness or recency of a given theory or viewpoint but from its capacity and economy to capture accurately and successfully and to address the needs, problems, and concerns of relevant African clients.

Ethical Principles

The African worldview provides an important guide to African psychotherapy and indeed for the successful practice of effective psychological therapies among African clients. Through a thorough knowledge of such a worldview, a lot of the problems which African clients bring up for attention become easily appreciated. This is because the African worldview profoundly permeates the African people's experience of the world and the way they give meaning to what affects their welfare in the world. In some cases, having a good knowledge of the African worldview helps to understand what needs to be done or the rituals to be conducted for healing to take place. Through the guide of such a worldview, important dos and don'ts in dealing with an African man or woman in the counseling context also come to light.

Yet, because the current African psychotherapists are often people of double socialization, a good number of them being well trained in both the Western models of psychotherapy and in the African way, most are members of psychotherapy associations scattered all over the world that abide by the *Ethical Principles of Psychologists and Code of Conduct* of the American Psychological Association (APA) and that of the *British Association for Counselling's (BAC) Code of Ethics and Practice for Counsellors*. African psychotherapists also abide by the principles of research ethics in the social sciences which emphasize the need for anonymity of respondents and for seeking the informed consent of these respondents before subjecting them to any research.

Key Values

In contrast to the nature of life in indigenous African societies, the modern African environment is characterized by the presence of an unpredictable world where people grow up with few definite guidelines on how to confront the problems of living. Increasingly bereft of the usual social support of the extended family

system and the typical cultural patterns of intervention in emergencies, people are constantly faced with enormous psychological brokenness and identity fragmentation (Gergen 1991), leading to social despair and demoralization. This arises from the complicated nature of the new cultural environment under which we live and work. Trained African psychotherapists endeavor to blend what is good in the healing systems of indigenous Africa and the West to fashion out an appropriate response to the psychological needs and problems of the contemporary African clients.

In particular, African psychotherapists do their work in full recognition of the kind of globalized influences that present challenges to the task of psychological adaptation of the modern African youth. In this regard, following the transformations wrought by colonialism, political independence, industrialization, and urbanization, as well as the missionary presence and Westernization of educational systems in Africa, the need for modern African psychotherapy has become intensified. The complicated nature of the new African environment compels the need for the use and application of psychological therapies (African and Western) and allied methodologies and frameworks that will enable the upcoming African youth to navigate the complex terrain of the complicated cultural, educational, and career worlds into which they have been embroiled.

Against the above, the effort and understanding of modern African psychotherapists (composed not only of trained counselors but also African novelists and poets) is that unless redirected, the emerging African youth may never be fully happy even in adulthood. In this way, the philosophy of African psychotherapy, as reflected in its various practice models (both critical and clinical), becomes an attempt to uproot or to facilitate the uprooting of the toxic factors (psychological, social, political, and cultural) in the modern African world. In the South African context, for instance, it was proposed that a more relevant indigenous counseling psychology must work to awaken the oppressed members of the black community to appropriate

political action and the counselor to conscientize all clients about the influence that sociopolitical factors have on their lives.

Conceptualization

Nature/World

African psychotherapy conceptualizes nature and the world from the perspective of the African worldview in which there is a belief that the entire universe is composed of three interdependent planes: the physical (material), the metaphysical (abstract), and the spiritual (transcendental) planes. Such a view of the world goes hand in hand with the African belief in the existence of mystical causality in the human world. In this perspective, humans are believed to live in the midst of invisible forces, to which they are mystically linked, which when provoked can visit them with anger and adversity, but when appeased and well served and disposed can bring them good fortunes and blessings.

Accordingly, African psychotherapists consider as incomplete, the Western individualistic picture of human beings as self-sufficient living systems, fundamentally determined in their basic motivation by the force of the pleasure principle, for, in the context of African worldview, an individual's life project is essentially multiple and broad-based in range and is worldly centered with the aim to achieve maximum success in various departments of life: life, health, wealth, offspring, and peace/joy (Nwoye 2005b).

Human Being

In African psychotherapy, a human being is conceived of as a complicated organism, simultaneously physical and spiritual in nature, and constitutive of multiple and interdependent dimensions that encompass the biological (the bodily), the social, the psychological (the heart, the emotional), the spiritual (the religious), and the metaphysical (the liminality, hopes, and beliefs) aspects. In African psychotherapy, in particular, the human being is conceived of

as a decentering subjectivity, rather than as a demarcated or bounded entity, walled off from the rest of the world (Nwoye 2006). Indeed, the common understanding in African perspective is that there is a dialectical interpenetration of the individual and the community in which neither has full primacy. Similarly, in African psychotherapy, there is a belief that within the metaphysical component of the African human being there exists a melioristic element, a *melioristic self* (Nwoye 2006) which acts as the individual's resident therapist for questioning misfortune, for responding to uncertainty, and for coping with the ordinary challenges and adversities of the African experience. Thus, the melioristic component of the African human being is the part of the human being which, in difficult circumstances, enables the individual to maintain psychological serenity by helping the individual not to fixate on the decadence of the present but on his or her own greater meaning or improvement that is yet to unfold. Another aspect of the metaphysical component of the human being as understood in African psychotherapy is the notion of its liminality. This refers to a recognition which is often celebrated in ritual form in Africa that every human being always lives in a state of liminality, that is to say, at the threshold of something, in which the individual is no longer one thing (e.g., a child), but still not yet another (an independent and self-supportive adult) (Nwoye 2006). The transcendental/spiritual element is the one that is assumed to be responsible for the widely acknowledged trait of exceptional religiosity in the African human being.

Based on the above, the Western notion of the self as a self-contained, imperial, and value-free agency in control of its fate in the world appears foreign to African psychotherapy.

Life and Death

African psychotherapists recognize and work with the view that the average African holds a precarious view of the universe. This means that they tend to attribute many forms of misfortune, illness, death, and failure to arise

from the activities of ubiquitous malevolent spirits, revengeful ancestors and forces of destiny operating through nature, and some evil human beings. This means that in African psychotherapy, there is recognition of the fact that humans are not in full control of their fate in the world. People come into the world not on their own behalf but from other people's (their parents') solicitations and decisions. But once born, the individual is expected to participate in the joint ownership of his or her life and to submit to training and normative guidance to benefit positively from the blessings of having earthly life and being in the world.

Reality

African psychotherapists acknowledge the existence of two levels of reality, visible and invisible or material and spiritual realms, both of which are interdependent in their relationship to one another. In this perspective, there exist both good and evil spirits as well as good and evil human beings, and everything in nature is either a manifestation of matter and, as such, is tangible, physical, and responsible for sensible perception, or supernature, that which is nature's hidden power and life. The perfect combination of the two levels of reality (material and spiritual) ensures the harmony and ordered progress of the African world.

Knowledge

African psychotherapists recognize in their research, theory, and practice that human knowledge is partial, historical, and evolutionary in nature and changes with time. They also believe that there are various sources of human knowledge. And they derive some of their working knowledge: from direct research on a given problem, from the wisdom of the sages, from interviewing and listening to clients offering own explanations and "theories" of the genealogy of their problems, from African and Western psychology, from African literature (oral and written), and from African art, African religion, African anthropology, and African archaeological finds.

Truth

African psychotherapy acknowledges and respects the existence of multiple perspectives to truth, including the existence of the phenomenon of complimentary duality in human contexts. By this is meant that in human life, nothing exists in complete isolation from one another and that when one thing stands, another stands beside it. In this perspective, there is no single road to truth, no royal road to success, or to good life. Thus, in the process of African approach to truth and reconciliation, four types of truth are sought for in the search for justice between opposing parties (Nwoye 2003). These include factual or forensic truth, personal or narrative truth, social or dialogue truth, and healing or restorative truth. These were the same four that were sought for and reported in 1998 by the Truth and Reconciliation Commission of South Africa.

Perception

African psychotherapists recognize that human behavior is influenced by the field as perceived or by the way things seem or feel to the individual or the group concerned. Human perception is therefore understood as phenomenological/perspectival or personal in nature and thus subject to human errors. African psychotherapists similarly believe in the evolutionary nature of perceptual competence in human beings. That is, that it gets better with age due to the influence of experience in the evolution of people's cognition; hence, the saying in most parts of Africa that *what the elders may see while sitting down, the youth may not see even while standing up*.

Time

African psychotherapists recognize that a special constituent of the African human being is its capacity for the abstract attitude, reflected in the individual's power to live and move in the shadow of the "thick present." This orientation refers to an African individual's capacity to hold in his or her present time consciousness the three dimensions of time: the "past present," the "present present," and the "future present" synoptically. In this way, the present state of the African individual keeps on reminding him or

her not only of the present situation (good or bad) confronting him or her but also of a past that has gone before and the future that is yet to unfold. Many African psychotherapists believe that this capacity for the abstract attitude, which promotes the African's capacity for a synoptic time consciousness, is a foundation for good mental health. It enables many people in Africa to live beyond the decadence and tribulations of their "present present" (Nwoye 2006).

Consciousness

One of the goals of African psychotherapy is expansion of peoples' consciousness in the form of psychoeducation. And there are several levels of human consciousness acknowledged and targeted for action in African psychotherapy. For instance, in African psychotherapy, enormous emphasis is placed on the development of extended family consciousness or the spirit of ► **ubuntu**, which although is often said to constitute a source of multiple pressure to provide for the needs of others in the modern African environment, yet is recognized as a source of moral and emotional strength in African traditions. Besides, the extended family consciousness plays the role in African traditions of reinforcing the individual's moral sense by making him or her constantly aware that his or her immoral actions will bring disgrace not only to himself or herself but also to the entire family and, through it, to the entire community among whom he or she is a part.

The crucial implication of the above is that in African psychotherapy, the successful life is not understood as one lived in self-sufficient isolation, in which the emphasis is toward greater self-sufficiency and independence of others, as often emphasized in the West. Rather, the notion of mature human development in African psychotherapy is conceptualized as one that is conscious of the interdependent nature of human beings from conception to death.

Rationality/Reason

African psychotherapists give due recognition to the place of rationality/reason in human life. But in African psychotherapy, it is acknowledged that

the most acceptable paradigm to guide practice is the one derived from quantum or post-Einsteinian physics which proposes that in their judgment of experience, people tend to go beyond the information given (to use Jerome Bruner's phrase (Bruner 1990)). This is an important insight in the context of African psychotherapy, in that Africa is a world where meaning that is given to events of life is influenced not always by rationality/reason but by the context and the grammar of the culture in which the individual is situated. This perspective implies that the African's universe is not an Aristotelian universe, but essentially an interpreted universe, implying a world of information and relationships dominated by the influence of local knowledge (Nwoye 2006). In this way, African psychotherapists acknowledge that in the experience of some of their clients, life can at times be larger than logic. Yet they also recognize that certain institutions like African marriage are built on a framework of order. In African marriage, the presumed order takes place if after marriage there comes childbearing, followed by childrearing/investment in children, and thereafter filial care and support of parents in old age.

Mystery

In African perspective, there is a belief in the existence of mystical causality (Nwoye 2005b, 2006) in the human world, reflecting an understanding in which mysterious happenings are seen to arise from unpredictable events and chance encounters. In that way, reasons for failure or success in this world are often interpreted to arise from the deliberate agency of inscrutable forces, which at times operate through the agency of evil-minded persons to cause disasters to targeted victims. A related belief to this conception is the attribution, still extant in present-day Africa, and which is often encountered in the context of practice of some African psychotherapists, that evil human beings can transform into dangerous animals like snakes, scorpions, and lions to kill their human enemies (Nwoye 2006). And some can mystically change into wild pigs to enter and destroy their enemies' crops or farm. This aspect of the African understanding of the

human condition is the one that is meant to suggest that in the African imagination, physical nature is not dead but, rather, is understood to be imbued with immanent vitality and spirit force. In the African view, there is a supernature underlying all aspects of nature, the spirit of which animates and infuses nature with mystical potency (Nwoye 2005b, 2006).

Relevant Themes

One additional issue or theme in African psychotherapy is the recognition and attention given to the influence of spirituality in the life of African clients. One implication of this is that a typical African client holds a number of religious beliefs that influences his or her way of living in the world. These include the following. First, there is a belief in the existence of the Supreme Being or a power from whom all good things come. This notion coincides with the important assumption in Africa that God is involved in the details of our human experience and that things do not happen unless God approves them. The same attitude encourages the great principle in Africa of resignation to God's will when confronted with problems that we can neither handle nor alter. Second, there is a belief in the existence of other spiritual agencies and in the capacity of these agencies to influence – positively or negatively – the course of human welfare in the world. This belief coincides with the notion that there is an intermingling of forces in the universe (Nwoye 2006).

Third, there is a belief that our ancestors and other deceased relatives, though dead, are still living (Mbiti 1969) – that like the gods, they need only to be venerated to be of service to us in challenging the problems of living. This notion goes with the idea of invisible loyalty that is ever present in the mind of a typical African, that the voice or directives of the ancestors and dead parents must be respected and adhered to. This aspect differs from the Western existential notion of the self as an unbounded, imperial, or a totalitarian subject that is invested with values and principles that are personally chosen (Nwoye 2006).

African Traditional Counselling

► [African Psychotherapy](#)

African Worldview

Augustine Nwoye

School of Applied Human Sciences, University of KwaZulu-Natal, Pietermaritzburg, South Africa

This refers to an African's perceptions of his or her world. In African psychotherapy, it is believed that Africans have a tragic sense of life (Madu et al. 1996). This means that in Africa there is a firm belief in the existence and operation of the power of unforeseen circumstances or unpredictable life events in influencing people's destiny in the world. In this perspective, human beings have limited agency rather than complete control of what happens to them in this world.

Description

The meaning of the expression “post-” or “after-metaphysical theology” is anything but obvious. Rather, the expression's omnipresence in postmodern theological circles rather appears inversely proportional to its transparency. The term covers a wide spectrum of dissimilar meanings and a certain amount of confusion therefore seems unavoidably present in any attempt to straightforwardly define this conceptual centaur. The term not only expresses a methodological position stressing the necessity of thinking somehow “after” metaphysics but also expresses a certain conception of our situation in the world. As such, “after-metaphysical” has become a key concept articulating a certain (but vastly divergent) philosophical and/or theological self-understanding. As an attempt to (in the words of Hegel) “apprehend our time in thoughts” (Hegel 1821, 26), the expression “after-metaphysical” seems to compete with and/or overlap a number of different, more or less idiosyncratic compound expressions such as “postmodern theology,” “postsecular theology,” “the end-of-metaphysics theology,” “deconstructive theology,” “theology after the death of God,”

“postliberal theology,” “feminist theology,” etc. (cf. Ward 2001; Vanhoozer 2003). Hence, the expression must be seen as a hybrid which covers a wide range of different movements or trends.

In his book, *Postmetaphysical thinking* (1992) (German: *Nachmetaphysisches Denken* 1988), Jürgen Habermas argues that the philosophical situation in the wake of Hegel’s speculative idealism (i.e., the “post-Hegelian situation”) does not differ significantly from our present age. In other words, the philosophical situation after Hegel has left us with no real alternative to an “after-metaphysical thinking” (Habermas 1988, 36). As regards theology, this after-metaphysical situation is reflected in the late-Enlightenment shift from “natural theology” (*theologia naturalis*) to a brand new philosophical discipline: philosophy of religion (Jaeschke 1992, 748). Even though, of course, it would be erroneous to identify “after-metaphysical theology” with “philosophy of religion,” it must be conceded that any attempt to think theologically without taking into account the different developments within philosophy of religion and modern science is untrustworthy. Thus, the dissolution of natural theology in the late-Enlightenment period may be said to offer a parallel to what Habermas refers to as philosophy’s after-metaphysical situation.

In any case, it is obvious that the exact meaning of the expression “after-metaphysical theology” not only depends on the understanding of what is meant by “theology” but also relies on the meaning of the other two elements contained in the expression: “after” and “metaphysical.” Whereas the meaning of the prefix “after” at a first glance may appear uncontroversial, the term “metaphysical” is notoriously ambivalent and controversial. The polysemic character of the term “metaphysical” threatens to efface any liable attempt to define the expression “after-metaphysical theology.” In order, however, to avoid making the expression unreasonably diffuse and vague, it seems necessary to unfold the different layers of meaning attached to the expression somewhat more in detail.

Metaphysical

Since the expression “after-metaphysical theology” is related explicitly to the notion “metaphysical,” it must first be clarified what is meant with metaphysical. The Greek expression *meta ta physiká* is a compound of the prefix *meta* meaning “after” or “beyond” and the substantive *ta physiká* meaning “physical” or “natural” and thus literally means something like “that which comes after or lies beyond the physical.” Even though this etymological “definition” on the face of it appears reasonably comprehensible, it must be remembered that the “physical” or “natural” is itself a metaphysical category which does not represent a constant in history. In relation to the question about “after-metaphysical theology,” the following three “aspects of metaphysical thinking” (Cf. Habermas 1988, 36ff) deserve particular attention since it is these aspects which are somehow critically refused or at least challenged by after-metaphysical theology:

- (a) *Identity*: Metaphysical thinking is guided by an attempt to reduce (literally: lead back) the manifold of experience to conceptual unity. The abstract relation between identity and difference is conceived both logically (“to give the grounds for”) and ontologically (as “foundation” or “basis”): The unifying principle of identity is both principle in the sense of “beginning” or “source” and in the sense of the stabilizing “ground” or “foundation” which underlies the manifold of reality. As “first philosophy” (*prima philosophia*), metaphysics is concerned with the “foundations” or the “principles” of “being *qua* being” (*Met.* 1026 a 32), a formulation which becomes a pivotal point in Heidegger’s account of metaphysics as ontotheology (see below). According to Deleuze and Guattari, the tree has become the predominant model of orientation in Western thought: “It is odd how the tree has dominated Western thought, from botany to biology and anatomy, but also gnosiology, theology, ontology, all of philosophy...: the root-foundation, *Grund, racine, fondement*” (Deleuze/Guattari 1988, 20). The roots of

Western (metaphysical) thought is to be found in its insistence on thinking within the model of the upright standing tree, thereby thinking being “vertically” (cf. Deleuze/Guattari 1994, 43). This aspect of metaphysical thinking is often referred to as “foundationalism” (cf. Green 1999, 2–3): The attempt to ground thinking on an incorrigible, firm foundation.

- (b) *Transcendence*: Metaphysical thinking is guided by the establishment of a “plane of transcendence” (Deleuze/Guattari 1988, 310). The abovementioned “ground” or “foundation” is thereby transferred to a realm “beyond” or “above” the immanently given. Nietzsche’s critique of the metaphysical tradition may be understood within this binary scheme: “Nihilism” is, in Heidegger’s interpretation of Nietzsche, “that historical process whereby the dominance of the ‘transcendent’ becomes null and void, so that all being loses its worth and meaning” (Heidegger 1982, 4). According to Heidegger’s interpretation of Nietzsche, the “death of God” constitutes nothing (!) but the dissolution or annihilation of every attempt to ground “being” in a transcendent level; a figure of thought which also resounds in Deleuze/Guattari’s claim that transcendence is a “specifically European disease” (Deleuze/Guattari 1988, 20), namely, the disease to interpret the “value” of life from a transcendent perspective.
- (c) *Order*: Metaphysical thinking is guided by the construction of a certain order which is to be understood both on an ontological and an axiological axis. The transcendent principle of identity is not only placed topographically “beyond” or “outside” the given but is also simultaneously declared “higher,” “better,” “more real,” “more true” than “the realities in which we live.” Such binary codes (good/bad/pure/unpure/essential/accidental, etc.) are not just, Derrida claims, “one metaphysical gesture among others, it is *the* metaphysical exigency, that which has been the most constant, most profound and most potent”

(Derrida 1977, 236). Thus, the “will to order” may be said to be an important facet of metaphysical thinking.

After

Even though the word “after” on the face of it appears harmlessly unproblematic, it does, on closer inspection, become quite unclear in what sense “after” should be taken when brought together with the word metaphysical. Already Heidegger’s project of a so-called *Verwindung* of metaphysics displays a fundamental ambiguity in relation to metaphysics: The process of *Verwindung* is neither identical with an “overcoming” (*Überwindung*) nor with a “leaving behind” but must rather be understood as a particular way of being related to the past in a “manner that (...) constitutes neither the acceptance of its errors nor a critical surpassing which would merely continue that past” (Vattimo 1987, 11). Inspired by Derrida, Mark C. Taylor has suggested the following understanding of the word “after”: “On the one hand, to come after is to be subsequent to what previously has been, and on the other hand, to be after is to be in pursuit of what lies ahead. Betwixt and between past and future, after is never present as such but is the approaching withdrawal and withdrawing approach that allow presence to be present” (Taylor 2007, 345). Nonetheless, the understanding of “after” remains a question: Does it mean that we have left something irrevocably behind us that we are definitively beyond metaphysics in the abovementioned sense? Would that not presuppose that metaphysics is indeed something “outside us” that we can divest ourselves of or “brush aside like an opinion” (Heidegger 1954, 72)? Moreover, to speak of “metaphysic” (in the singular, definite form) may be rhetorically appealing, but it suffers from a tendency to “liquidate the particular” (Adorno 1951, 15), thereby representing the exact same tendency toward “totalization” which it so passionately criticizes. Finally, it should be noted that the very discourse of the “end” (or, as a possible implication, “the return”) of metaphysics (or of “God”) *itself* seems to constitute a significant metaphysical line of reasoning.

After-Metaphysical Theology

Of particular importance for the understanding of “after-metaphysical theology” is the term “ontotheology.” Kant first introduced this *terminus technicus* in his *Critique of pure Reason* (1781/1787) as a term used to describe a particular type of theology which deduces the existence of God by “pure” concepts, i.e., concepts having no appeal to experience (Kant 1998, 556 (B 659)). Since then, the sense of the term has been expanded quite significantly by Heidegger and Derrida (Hart 2000, 75) so that all metaphysics fundamentally is “ontotheology” because it is the forgetfulness of the (ontological) difference between being and beings (Heidegger 1957, 59): “metaphysics is defined as the question about beings as such and as a whole. The wholeness of this whole is the unity of beings, the ground that brings them forth and unifies them. To anyone who can read, this means: metaphysics is Onto-Theo-Logy” (Heidegger 1957, 63). This identification of metaphysics (as such) with ontotheology raises the question whether it is possible to formulate a “nonmetaphysical theology” (Hart 2000, 75) which finds itself outside the area of ontotheology. Such an attempt has been pursued by, e.g., Gianni Vattimo’s “weak thinking” insisting on the structural similarity between the incarnation (understood as a nonviolent “kenosis”) and the “weakening of strong structures of being” attested to by after-metaphysical thought (Vattimo 1997, 40) and Merold Westphal’s endeavor to “overcome ontotheology” by means of a radically hermeneutical approach (Westphal 2001). In any case, the problem of a “negative dialectic” or “dependency” between the “overcoming” and that which has been overcome cannot easily be left aside (cf. Adorno 1966, 373) and the question therefore remains: Can we avoid thinking metaphysically; in which sense is an “after-metaphysical theology” altogether possible?

Empathy

Common usages of the words “Eros,” “agape,” and “altruism” overlap in important ways. They are all used to connote a certain direction and substance of desiring or willing. It is a direction toward the other. And it is for the good of the other. Furthermore, ordinary use of the word *altruism* presupposes a threshold degree of intentionality. That is, the altruistic person is supposed to be aware of herself (self-consciousness) and of her positive regard for the other. The following interpretation of the concept of altruism is close to the ordinary use of the word.

Besides important overlapping aspects, in contemporary Christian ethical discourse as well as in Freudian Psychology, the words “Eros” and “agape” are also used in contrasting ways. Here, Eros connotes a desire, often supposed to be sexual in kind, to possess or enjoy the other. This usage of the word “Eros” suggests that both the direction and the substance of “Eros desires” are somewhat ambiguous. Desiring to enjoy another person does undoubtedly involve her or him, but it is not directed toward her or him in any other sense than as an instrument for the desiring subject. It is understood as more similar to the coveting of a piece of chocolate than to positive regard. The satisfaction of a desire to enjoy is something that solely happens to the desiring subject; it is self-regarding.

Other regarding desires in contrast are defined by a wish that something goes well or that something bad happens to the other. The

word “agape” is used by many Christian theologians to connote the particular other-regarding and self-giving love of the Christian God (e.g., cf. Anders Nygren, Gene Outka, and Timothy P. Jackson). The supposed self-giving nature of the love of God means firstly that it is supposed to flow out of the loving subject independently of any kind of reward. Secondly, agape is allegedly not conditioned by any possible merit or worthiness of its object. One possible merit could be that loving someone is in fact rewarding. Nevertheless, love can in principle be bestowed on deserving objects independently of whether loving the deserving is in any sense rewarding, and most theologians claim that loving independently of reward is better than if love would be conditioned by reward. Thirdly, agape is not only characterized by being unmotivated, it is also supposed to have the power and function to bestow value on its objects (e.g., cf. recent work by Nicholas Wolterstorff). Among contemporary theologians, this value is thought of as very high and as equal between all individual human beings. It is therefore also often labeled human dignity. It is worth noting here that equality does not belong to the concept of agape. It is used as an addition or qualification of the character of God’s love. It makes perfect sense to start explaining the meaning of God’s love by saying that God loves everyone equally. But the concept of agape is not similarly needed for the explication of the meaning of the concept of equality.

Finally, the word “altruism” has usages that usually differ in primarily two ways from the mentioned theological interpretations of both Eros and agape. In ordinary use, altruism is not supposed to have the function of constituting value. It, however, is not self-regarding either, like some claim Eros is. Like “agapist” action, altruistic action is not supposed to be motivated by merits of its object. Nor is it motivated by personal reward other than the simple satisfaction of the desire to do good for the other (which does not count as an ulterior motive). In recent Christian normative animal ethics where the

ingredient of bestowing value is downplayed, agape is oftentimes understood as synonymous to altruism. Thus, one can say that the concept of altruism contains the first two basic elements of classical theological interpretations of agape.

Agency Detection

Matt Rosano

Psychology Department, Southeastern Louisiana University, Hammond, LA, USA

Ascribing behavior to an internal mental state such as a desire, goal, or intention. Agency detection is the first, necessary step for developing a theory of mind (TOM) where one understands others to have beliefs and inferences based on his/her particular perspective of the world. There is some evidence indicating that nonhuman apes may understand others as intentional agents and may even possess a limited form of TOM. However, this is controversial and continues to be a topic of research and debate.

[Belligerence](#); [Violence](#)

Definition

Aggression is a complex concept historically rooted in social psychology, anthropology, and psychoanalysis. It encompasses behavioral (fighting), emotional (anger), and cognitive-

motivational (aggressive thoughts and goals) aspects resulting from a combination of genetic, neurobiological, endocrine, and social processes. Often reduced to the behavioral component, aggression is understood as the intentional physical harm of another person. Recent research acknowledges indirect forms of aggression such as social exclusion. The term violence is usually used for a subset of aggressive behaviors that are severe in nature, e.g., physical fights with dangerous objects or robberies that inflict severe psychological harm. The World Health Organization defines violence as “the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment, or deprivation” (World health organization 2002). Although most often seen as a violation of social rules and norms, aggression is also sanctioned by societies in the case of war, revolution, certain sports, media, and the arts. Due to a lack of a unified concept, the field of psychiatry does not identify aggression as a distinct diagnostic category but rather as a symptom prevalent in many different mental illnesses such as antisocial personality disorder, borderline personality disorder, intermittent explosive disorder, and conduct disorder.

Types of Aggression

Current research supports the validity of subtypes of aggression. The most common distinction is drawn between reactive and proactive aggression (similar to affective vs. predatory aggression). Reactive aggression is executed in a state of increased emotional and autonomic arousal following a frustrating or threatening event. Proactive aggression is intentional, goal-directed behavior to obtain a desired outcome such as social dominance or money and has been associated with psychopathy. Empirical data has shown that there are two groups of aggressive individuals, those that present with reactive aggression and those that present with reactive and proactive aggression.

Social Correlates of Aggression

A major root of aggression is the relationship of the individual with her social environment. Several psychological mechanisms are known to be involved in the development and maintenance of aggression, including instrumental learning (aggressive behavior controlled by reward and punishment), social learning (observation and imitation of others' aggressive behavior), priming (e.g., weapons effect), desensitization (emotional blunting and changes in thoughts and beliefs), aggression-frustration (response to a frustrating event), and enacting (engagement in virtual aggressive behavior). Two research lines on the influence of social factors on aggressive behavior are described below as examples.

Aggression and Media Violence

Violent media is available to individuals of all ages. Hundreds of laboratory, retrospective, and longitudinal studies suggest that exposure to violent TV programs, horror movies, songs with graphic lyrics, and violent video games is associated with aggression. The exposure to these media facilitates physical aggression, anger, hostile thoughts, perception of violence as common and inevitable, and perception of the world as a mean and dangerous place and decreases prosocial behavior and empathy toward victims of real-life violence. Video games have been the focus of recent research because they portray violence in increasingly realistic settings and engage the player proactively in aggression. Long-term changes associated with exposure to violent media are thought to develop through observational learning, enactive learning, and desensitization. Violent media is usually presented without criticism, expression of remorse, or long-term negative consequences thus promoting the justification of aggressive acts. Other factors that moderate these effects are personality variables, e.g., predisposition for aggressive behavior and identification with the aggressor, as well as the context in which the media is consumed (Huesmann 2007).

Aggression and Religion

There has been a recent research interest in understanding violence in religious movements and appreciating the psychosocial dynamics of religious belief. Throughout the history of mankind, religious beliefs have been exploited to justify and drive war and violent attacks. It is assumed that religious people have a set of beliefs about the will of god and how to execute it and that these beliefs guide social behavior. First experimental findings indicate that violence portrayed in scripts and sanctioned by god increases the risk for aggressive behavior through processes of justification and identification (Bushman et al. 2007). Further studies are needed to investigate the link between religion and aggression, such as in-group identification and aggression toward out-groups and the cognitive processes underlying militant extremism and the refusal to tolerate divergent worldviews.

Development of Aggression

There is evidence suggesting that aggressive behavior develops along distinct trajectories: An early-onset form of aggression that starts in early childhood and persists well into adulthood and a later-onset form that is limited to adolescence and early adulthood (Moffitt et al. 2002). Regardless of the trajectory, risk and protective factors for aggression differ depending on the developmental stage. Early risk factors include child fighting, victimization, childhood substance use, inconsistent or harsh parenting, and family conflict. During adolescence, poor relationships with peers, gang involvement, and living in a violent neighborhood become significant risk factors for the development of severe aggressive behavior. Protective factors such as competent parenting skills, including monitoring, consistent discipline, and supportiveness, may reduce the likelihood of engaging in aggressive acts during childhood, adolescence, and later in life (National Institutes of Health 2004).

Recent advances in neuroimaging and other biological research can potentially promote the understanding of factors that contribute to the

development of aggression. For example, longitudinal research on structural changes in the prefrontal cortex – a region of the brain that has been associated with aggression – revealed that prefrontal cortex gray matter thickens until about age 11 and then begins to gradually decrease, currently thought to result from a combination of synaptic elimination and increasing white matter volume from myelination. Another neural system that undergoes significant changes during adolescence and that has been intimately linked to behavioral adaptation through reward and punishment is the dopaminergic system of the brain. To date, it is largely unknown how these morphological changes affect brain function and subsequently aggressive behavior in interaction with environmental influences during adolescence (Blakemore 2008).

Biology of Aggression

Neurotransmitters

Although neurotransmitters such as GABA and glutamate have been discussed in the literature, the most prominent neurotransmitter that is associated with aggression and violence is serotonin. Decreased brain serotonin activity as a correlate of aggression has been shown in studies employing chemical serotonergic indices, pharmacological challenge with serotonin agonists, functional imaging, and genetics. Compelling results in psychiatric populations with elevated levels of aggression revealed that depletion of the serotonin-synthesizing tryptophan increases aggression, whereas the administration of serotonin reuptake inhibitors decreases aggression. Furthermore, serotonergic stimulation increases metabolic responses in the prefrontal cortex, a region that has been associated with aggressive behavior and that has abundant serotonin receptors. It has been proposed that variations in serotonergic activity are particularly linked to impulsive aggression and investigations of normal variations of aggression in healthy individuals indicate a broader role of serotonin in self-control and goal-directed behavior (Manuck et al. 2006).

Genetic Aspects of Aggression

Twin and adoption studies have shown that violence has a heritable component. However, results from studies in the 1970s on chromosomal abnormalities in prisoners could not confirm the causal influence of the XXY genotype on aggressive behavior. Rather, modern molecular genetics research indicates that polymorphisms in neurotransmitter metabolizing enzymes are a fruitful approach to investigate the link between genetic dispositions and violence mediated through individual differences in neurocognitive functioning. For example, it is known that the low expression variant of monoamine oxidase A, a crucial enzyme in the serotonin catabolism, is involved in emotion processing and cognitive control and increases the risk for impulsive aggression (Meyer-Lindenberg et al. 2006). There is, however, an interaction between genetic polymorphisms that can increase the risk for aggressive behavior and childhood upbringing. The low expression variant of the serotonin transporter 5HTT generally increases the risk for aggressive behavior particularly in the context of an adverse childhood environment, but a supportive childhood environment suppresses the risk for aggression in the presence of the low expression variant of 5HTT.

Brain Structure and Function

Modern, non-invasive neuroimaging methods have stimulated the study of structural and functional correlates of aggression and violence. The prefrontal cortex, insula, and the amygdala – a gray matter structure underneath the cortex that helps weigh the emotional relevance of stimuli – have been linked to aggressive behavior. The amygdala is thought to be involved in the basic threat circuit and has a role in increasing or decreasing the likelihood of aggression in response to a threatening or frustrating event. Damage to the orbitofrontal and ventromedial prefrontal cortices, both parts of the prefrontal cortex, has been shown to increase aggression in patients with penetrating and other head injuries, and it has been argued that these structures are involved in the exertion of inhibitory control over aggressive impulses (Blake and Grafman 2004). Studies

investigating the association between behavioral measures of aggression and gray matter volume indicate that decreased prefrontal cortex, or increased amygdala, and insular volumes are associated with aggression in aggressive psychiatric patients, aggressive interactions between healthy adolescents and their parents, and symptoms of aggression in conduct disorder, respectively. Functional imaging studies revealed that reduced levels of activation in the ventromedial prefrontal cortex are linked to aggression in healthy individuals (Meyer-Lindenberg et al. 2006).

Treatment of Aggression

There has been a paradigm shift in the treatment of aggression from “nothing works” in the late 1970s to “some things work in some settings with some people” in the early 1990s. Despite limitations, there are several pharmacological options available for symptomatic treatment. Double-blind placebo-controlled studies and clinical experience indicate that mood stabilizers, anticonvulsants, antidepressants, antipsychotics, benzodiazepines, and beta-adrenergic blockers are useful agents for the treatment of aggression. Some of these agents, e.g., serotonin agonists and mood stabilizers, have a more direct effect on brain systems that modulate behavior and that have been associated with aggression including the prefrontal cortex. However, it cannot be determined today to which extent these agents are effective due to their antiaggressive impact rather than to their nonspecific sedative or neuroleptic effect, and there are currently no drugs available that primarily target aggressive behavior (Comai et al. 2012).

While pharmacologic agents can be helpful in reducing aggression, a combination with psychotherapeutic strategies is usually indicated to achieve long-term reductions in aggressive behavior. The successful implementation of psychotherapy depends on a number of variables including age, diagnosis, cognitive capability, severity of family dysfunction, and the willingness of the individual to engage in therapy. Children and intellectually challenged individuals typically profit from behavior modification

techniques and modeling of behavior, while adolescents and adults may benefit from more cognitive methods and dynamic psychotherapy due to their better insight. According to the NIH State-of-the-Science Consensus Statement for Preventing Violence and Related Health-Risking Behaviors in Adolescents, treatment that is most effective is characterized by the following criteria: it is based on sound theory, intensive and long-term, multimodal and multicontextual, developmentally appropriate, delivered with fidelity and in a noncoercive setting; it targets strong risk factors and the improvement of social skills and other relevant competencies and follows a cognitive-behavioral strategy. Without hesitation, these factors can be transferred to the treatment of aggression in adults (National Institutes of Health 2004).

Summary

Aggression is harmful behavior that directs physical attacks, angry feelings, and hostile thoughts toward other people. While some individuals display aggression only during adolescence, others develop notable violent behavior starting in early childhood. Through a combination of observational and instrumental learning, priming, desensitization, aggression-frustration pairings, and enacting aggressive thoughts, cognitive-emotional and behavioral patterns of aggression are formed. Children and adolescents are at particular risk for aggression when they face adverse family conditions, peer relations, and neighborhoods. Biological risk factors impact aggressive behavior in interaction with social mechanisms. Genetic predisposition and brain damage can set the stage for cognitive and social dysfunction in prefrontal and subcortical regions that lead to an increased likelihood of aggressive behavior. Pharmacological agents can help decrease aggressive symptoms in some patients, while behavioral therapies (sometimes in combination with drugs) can reduce social risk factors and foster interpersonal skills in other individuals.

Aging

Gisela Labouvie-Vief¹ and Pierre-Yves Brandt²

¹Department of Psychology, University of Geneva, Geneva, Switzerland

²Faculty of Theology and Religious Studies, University of Lausanne, Unil-Dorigny, Lausanne, Switzerland

Description

Interest in all aspects of aging has rapidly grown for about 60 years, with the dramatic gains in health, population growth, and longevity and the increasing number of aging individuals worldwide. Neuropsychological aspects of aging are treated as part of, or as subdisciplines of a variety of disciplines such as psychology, psychiatry, medicine, and neuroscience. The respective subdisciplines attempt to understand the relationship between psychological aspects of aging and their relationship to neurological processes, especially, the functioning of the brain. An overarching endeavor is to understand and describe the aging process, and to search for mechanisms related to aging as distinct from earlier development. For example, earlier development appears to be primarily driven by processes of genetic regulation and cultural efforts that encourage negentropy or the formation of increasingly complex structures, but aging and ultimately death are seen to reflect entropy, the lowering of the orderliness of structures that results when the effectiveness of these regulatory processes ceases. These processes are in part “natural” but across many of the aging subdisciplines, increasing emphasis is based on conceptualizing aging not merely as a normal process of deterioration and decline. Instead, increasing interest focuses on the mechanisms that may accelerate or slowdown aging and to understand ways in which deterioration can be prevented and or ameliorated, as well as competencies that may even improve in later life. A particular strong

current interest in the modifiability of patterns long associated with normal aging combines many of the subdisciplines, with an emphasis on the potentials and limits of the plasticity of the aging process.

Self-Identification

Science

The study of aging identifies itself as a science in the sense that it uses qualitative and quantitative research methods of the human and experimental sciences, such as biology, medicine, cognitive science, neuroscience, psychology, and sociology.

Religion

The study of aging includes research on the effects of religion and religious practices on such outcomes as psychological and physical well-being. As an example, one recent strong current interest is research on the effects of meditative practices on cognitive and emotional processes as well as health.

Characteristics

The study of religion and aging is part of the larger domain of religion and development (over the total life span) but interests itself primarily in the relationship between aging and religion, although some studies propose a view of a continuous process from birth to death.

Relevance to Science and Religion

This subdiscipline is interested in the scholarship of “Science and Religion” in the sense that it contributes empirical data about individuals’ religious beliefs and practices and their relationship to diverse outcomes, ranging from physical to psychological health. In that effort, a central question is to describe the specific forms and aspects or religiosity in elders that may foster or hinder well-being.

Sources of Authority

As is true of other sciences, the sources of authority are based on published research that is rigorously selected through a process of peer review in research funding and publications. A large variety of major scientific journals is devoted to or includes research and theoretical writings on aging; some of these journals focus specifically on aging and religion. A large number of regularly reissued handbooks further offer state-of-the-art reviews of the field.

Ethical Principles

Like other empirical studies, research of this discipline is subject to institutional ethical reviews which assure the safety, dignity, and entirely voluntary nature of research participation.

Key Values

The key values, like those of other scientific disciplines, focus on objective inquiry while at the same time respecting the rights, dignity, and safety of research participants.

Conceptualization

Nature/World

Nature and world are defined in terms of natural biological, psychological, social, and physical processes, and aging is seen as a natural process of biological, psychological, and social changes.

Human Being

The human being is seen in terms of genetic and physical dimensions and as encompassing psychological needs and propensities that lead him or her to construct meanings within complex social organizations; these psychological propensities are related to (i.e., in part derive from and in part influence) his physical and biological capacities, resulting in a basic view of evolving individuals equipped with plasticity.

Life and Death

Life is seen as a process of evolution that involves interaction of the individual with his or her social and physical environment and that is in part shaped by genetic mechanisms. Death is seen as a natural end of life but its quality is shaped by medical, social, and psychological dimensions. Psychologically, individuals' inner attitude toward and preparation of death, includes processes of grief related to the death of others or of one's own anticipated death.

Reality

Reality, like time, is in part subjective and constructed, in part objective and externally given.

Knowledge

Knowledge is seen to comprise not only quantitative accumulation, but also personal structuring of experience.

Truth

Truth is seen from both an objective perspective as consensus, and also from a subjective perspective as individuals' construal of beliefs, etc., held to be inalienable.

Perception

The field studies changes in the sensory perception (vision, hearing, taste, etc.) that are seen to be part of the process of aging, but perception is also used to refer to the personal and social construction of these meanings.

Time

Time is seen as a mere chronological passage but over and above mere chronology, also the way in which psychological-inner and physical-outer dimensions (e.g., social experience, environmental pollution) work to delay or accelerate time-related processes.

Consciousness

Consciousness refers to individual's awareness of self and others and their capacity to use reflection as a means of change. Consciousness is an

important area of study on many dimensions from psychological to neuroscientific.

Rationality/Reason

Reason refers to objective aspects as cognitive capacities and their changes with age as well as to more subjective aspects such as individuals' own reasoning on aspects of self and the world.

Mystery

This term is used little if at all in the field of Aging and Religion.

Aging and the Life Course, Sociology of

Duane F. Alwin

Department of Sociology, Pennsylvania State University, University Park, PA, USA

The subfield of the discipline of sociology referred to as “Aging and the Life Course” is concerned with understanding the interplay between the development of human lives and changing social structures across the entire span of life. Human development is considered as a multidimensional and multidirectional phenomenon within a broad framework that extends across the entire life span, from conception to death (see Baltes 1987). Historically, the concept of “aging” refers to changes to individuals in older age that occur over time resulting from some combination of biological, psychological, and social mechanisms. The “life span developmental” perspective is a somewhat broader framework, as it considers ► [aging](#) to begin at conception and conceptualizes human development as multidimensional and multidirectional processes of growth (or change) involving both gains and losses across the life span. From this perspective, human development and/or aging are embedded in multiple contexts and are conceived of in terms of dynamic processes in which the ontogeny of development interacts with the social environment, a set of interconnected social settings, embedded in a multilayered social and cultural context. In addition, the uniqueness of individual biographies and the diversity of life patterns have encouraged a “life course” approach to human development within the social sciences.

The life course can be defined narrowly, focusing on the unique pattern of events, transitions and trajectories of roles, or social pathways, extending across the life span, such as entering and leaving school, acquiring a full-time job, marriage, divorce, retirement, and the like (Elder 2000, p. 1615). Social pathways are discrete trajectories of roles followed by an individual through particular life stages, or between life stages, through time, for example, the transition from adolescence to adulthood may follow a variety of different social pathways. Or, equally common, the life course perspective can be seen as “an approach to the investigation of the changing environment of the individual and its developmental implications (see above) . . . through an evolving concept of age-graded life course that is embedded in a matrix of social relationships, an active view of the individual shaping the life course, and an approach toward understanding the historical influences in lives and developmental processes” (Elder and Shanahan 2006, p. 968). A number of concepts have been applied interchangeably – life span, life course, life cycle, and life history – but each of these makes a distinctive contribution that often has different meanings across disciplines (see Elder 2000; Alwin 2012).

The purpose of the life course *approach* is to examine the interdependence between (a) human development over the life span as a process that includes socio-environmental (as well as biological) factors and (b) societies and groups as stratified by life cycle stages, often socially constructed, which give meaning to temporal sequences of roles, (c) with succession of birth cohorts as the link connecting the human development and age-statuses. This special field draws, not only on sociology, but on the disciplines of anthropology, psychology, economics, and history, with an multidisciplinary perspective that contributes to the reformulation of traditional emphases on process and change, on the multiple interdependent levels of the social system, and on the multidimensionality of outcomes of interest as they touch on related aspects between disciplines (see Featherman 1983). The field is concerned with both basic scholarly research on aging and human development, as well as the

implications of this body of work for public policy and professional practice.

One important focus of the life course approach is the study of the social pathways defined by events and transitions experienced by individuals and the sequences of roles and experiences followed by individuals over particular phases of their lives (see Mortimer and Shanahan 2003). Influences of development, maturation, and aging are usually identified with changes within individuals linked to their getting older, becoming more mature due to having lived more of life, having experienced a variety of different life course events, or due to physical, cognitive, or other kinds of developmental change. For simplicity, we often refer to all of these types of “within-person” change as the effects of (or consequences of) aging, but it is an important emphasis of the life course approach to understand that these changes occur in a *social context* defined by the individual’s unique configuration of roles and the nature of the social environment. Human development and aging do not necessarily follow exactly the same course for all individuals and the life course perspective presents an approach to studying the variety of life course patterns.

One fundamental aspect of the social context experienced by the individual is the historical location and/or participation of those born at the same time. Indeed, one important premise of the life course perspective is that individuals are both producers and products of a complex historical and socioeconomic context through which their life experiences are shaped and understood. The concept of *cohort* is essential to this perspective in that it provides a mechanism for identifying and interpreting the potentially distinct collective characteristics of individuals who share a common year of birth. These distinct characteristics are commonly referred to as “cohort effects,” and their empirical identification is a subject of considerable interest. In life course and human development research, the common time interval defining the cohort is often one calendar year, and the shared event is birth. Thus, a birth cohort (often shortened to just “cohort”) is the group of people sharing a common year of birth. Members of a birth

cohort have the distinction of potentially experiencing a shared history inasmuch as they are the same age at any given point in time and, thus, share a common set of political, social, and cultural events at approximately the same point in the life cycle.

Finally, another important element in the life course approach is that people's lives are uniquely shaped by the timing and sequencing of life events (both intended and unintended), and that early life events and exposures contribute in meaningful ways to later life outcomes. Various strands of individual life trajectories, (such as schooling, work, military service, marriage, family, wealth, and health) are interconnected to one another, and it is assumed that events occurring in one domain can affect outcomes in another. This is implied by the fact that lives are embedded in institutional structures and historical contexts, and distinctive birth cohort experiences are considered to reflect exogenous influences. Not only are lives linked across generations, they are also linked intra-generationally.

The Scientific Study of Aging and Life Course

To understand how earlier life events and exposures influence the present and future, it is important to have accurate information about both the past and the present. How do students of aging (human development) and the life course gather information in an effort to study the causes and consequences of within-person change within a socio-environmental framework? Several different approaches have been used by researchers interested in the causes and consequences of within-person change with respect to outcomes of interest, outcomes typically related to health, disability, psychological well-being, or cognitive functioning, but the emerging consensus among students of aging is that research designs that collect measurements on the same persons over time are a particularly valuable approach to studying the causes and consequences of aging. However, any research design that locates and

measures events and processes in time is referred to as *longitudinal*.

Table 1 (below) depicts four different types of research designs – three of which are clearly longitudinal designs – that can produce potentially valuable information about aging and its consequences. One-shot cross-sectional studies (upper left-hand quadrant) can provide information on critical differences of groups of persons of different ages, but such studies provide a weak basis for drawing inferences about the processes of aging. While the limitations of such designs are increasingly recognized, they are pervasive in inquiries on aging. Two types of studies are typical of this type of design: (a) surveys of a cross section of the population are undertaken in order to compare persons born at different times (i.e., persons of different ages) in order to draw conclusions about the role of age in association with other variables, such as attitudes toward certain social policies, and (b) laboratory studies of cognitive aging, where a group of subjects (usually students) representing “young” people are compared to a group of subjects (usually older volunteers) representing the “old” and on the basis of observed “age differences” conclusions are drawn about “aging.” In this case, “between group” differences are viewed as reflecting the nature of “within-person” change that occurs with age or development.

There is a variety of other kinds of longitudinal designs, including everything from complicated life-history calendars, which go to great lengths to date events, their timing and duration, on the one hand, to retrospective life histories presented in narrative form, on the other. Often these can be embedded in one or the other of these four major types of designs, including the one-shot cross-sectional study, so even this design can ultimately be construed as longitudinal if it captures events and processes retrospectively (see Belli et al. 2009).

One of the critical problems with the one-shot cross-sectional studies in drawing inferences about the influences of “aging” is that they confuse these with the influences of “cohort” factors (Mason and Fienberg 1985). Persons of a particular age at a given point in time are also

Aging and the Life Course, Sociology of,
Table 1 Designs for the study of aging

<i>Single cross-section design</i>	<i>Repeated cross-section design</i>

<i>Longitudinal single cohort design</i>	<i>Longitudinal multiple cohort design</i>
Single cohort of persons observed over time	Multiple cohorts of persons observed over time

members of the same birth cohort (i.e., persons born during the same year). Members of a particular birth cohort share the experience of the life cycle, that is, they experience birth, infancy, and childhood; reach adolescence; grow into early adulthood; and mature into mid-life and old age during the same historical time. In this sense, members of a birth cohort share a social history, that is, they experience the same historical events and the opportunities and constraints posed by society at a given time in history. A person's *cohort* membership may be thought to index the unique historical period in which a group's common experiences are embedded, and their behavior may have as much to do with their historical experiences as they do with their age.

It is important to realize that one-shot cross-sectional designs are *not* inherently limited, especially if they involve the replication of cross sections over time. The existence of *diachronic* cross-sectional data for the same cohorts (see upper right quadrant) can be used as a legitimate basis for separating the effects of aging and cohort effects under certain circumstances (Mason and Fienberg 1985). Another way to control for cohort differences is to study a single cohort (lower left-hand quadrant of Table 1). Eaton (2002) provides a strong rationale for studying a single cohort from conception to death. In this type of single-cohort study, age variation occurs over time rather than cross-sectionally, and this permits an explicit focus on within-person change. However, development and aging do not occur in a historical vacuum, and while studying a single cohort over time does

hold many variables constant, it is difficult to generalize about processes of aging because of the confounding influences of aging and history.

Having information on the same persons across a range of birth cohorts opens up several possibilities for analyzing the effects of aging across cohorts (see the lower right-hand quadrant of Table 1). The value of this type of longitudinal design is borne out by the vast number of research projects over the past few decades that locate and measure events and processes *in time* (see Kuh and Ben-Shlomo 2004). Indeed, we have reached a point where there are several longitudinal data sets that permit the study of patterns and processes of aging in different historical and cultural contexts. For example, in the United States, the series of panel surveys known as the Health and Retirement Study (HRS) provides a series of replicated longitudinal studies of a sequence of birth cohorts currently and in the future. The first of these began in 1992 as a panel survey of persons from cohorts born in 1931 through 1941 and reinterviewed biennially since then. The idea for the HRS derived from a growing awareness of the inadequacy of data available from the Retirement History Survey that began in 1969 and followed a set of cohorts of men and unmarried women born in 1906 through 1911 for 10 years. Basing one's inferences about processes of aging, it was argued, on such a limited spectrum of historical cohorts had obvious limitations, given, for example, the growing participation of women in the labor force and related changes in the family. The collection of data on health and other antecedents of work and retirement decisions for more recent cohorts was viewed as essential to understanding experiences related to processes of aging in the more contemporary social context. The HRS design is one that studies multiple cohorts over time, sometimes referred to as an *accelerated* longitudinal design.

The assessment of change over time is fundamental to the quantitative study of aging, and longitudinal designs are vastly superior to cross-sectional studies in their ability to reveal causal influences in social processes because they can better pinpoint the temporal order of events, conditions, and experiences. For example, consider

the explosion of research interest in the relationship between socioeconomic status and health (see Alwin 2012; Alwin and Wray 2005). Many of the existing studies on this topic are cross-sectional and not necessarily suited to the kind of causal analysis that is necessary to understand the SES-health connection. In cross-sectional studies, it is possible to observe a substantial association between indicators of SES and measures of health, but this research strategy is quite limited because it ignores the dynamic processes of social stratification. For example, few studies measure both health in old age and health status at earlier points in the life cycle; therefore, it is difficult to know the extent of “within-person change” in health status, or how stable individual differences in health are over the life span. Studies that measure health at midlife or old age rarely include measures of early health status, or of early socioeconomic life experiences and family background. It is well known, for example, that early educational attainment, which is influenced by parental socioeconomic characteristics, shapes later life occupational opportunities as well as the economic consequences of those attainments.

Using a life course perspective, along with longitudinal data which measures early family background and relevant childhood socialization experiences, it would be possible to better sort out the extent to which the SES-health linkage is largely causal, or in part spuriously due to a range of “selection” factors that index events and experiences occurring earlier in the life course. Of course, even the best longitudinal data are unlikely to firmly resolve many substantive issues of this sort, in that there will still be relevant variables that are omitted from the design, limitations of sampling, measurement imperfections, and other impediments to drawing causal inferences. On the other hand, longitudinal data permit one to address far more interesting questions than is possible with cross-sectional data. For example, continuing with the SES-health linkage: How do early health deficits affect life-long socioeconomic outcomes? Do the advantages and disadvantages linked to one’s family background differentially affect current

health status, and what processes transmit these effects? Does the linkage between SES and health change over historical time (e.g., are younger cohorts less disadvantaged by early health deficits)? Do changes in (physical and mental) health status contribute to the loss of social status or social capital? Do changes in cognitive and/or emotional well-being shape decisions to exit the labor force, or retire, and therefore influence one’s social status? These are just some of the types of questions that could be answered with data from longitudinal designs, about which one can only speculate from relationships observed in cross-sectional designs.

Longitudinal data are also essential for examining issues linked to life course theory, which focuses primarily on the developmental or age-related patterns of change over the life span that are embedded in social institutions and subject to historical variation and change. However, in research on aging and the life course, there are several major impediments to drawing inferences about change and its sources. Perhaps the most fundamental of these is to be able to locate events and processes in time and specify their causal relation to consequences or outcome variables, while taking other causal factors into account. Thus, in research on aging, virtually all the best designs for studying life course phenomena are *longitudinal* because they allow one to more accurately conceptualize the nature of the substantive phenomenon and locate lives in time. This requirement strongly implies the need for repeated longitudinal studies based on sequences of birth cohorts, or what is often referred to as the accelerated longitudinal design (see Alwin and Wray 2005).

Finally, longitudinal designs also fit well with the newer perspectives linking the demography of the life course to human development. If one takes a life span developmental perspective with respect to the study of processes of aging (including life cycle processes and life course events and transitions) and recognizes that human lives are embedded in social and historical contexts, it is clear that a range of ontogenic and sociogenic factors impinge on people’s lives in ways that affect their well-being. Capturing the

interlocking trajectories or pathways across the life span that are marked by sequences of events and/or social transitions which impact upon individual lives and relating them to measures of health and functioning (among other things), as well as linking them to underlying social processes, is an important focus of a great deal of research on aging, and these are the major theoretical concerns that drive the present discussion of longitudinal methods for the study of aging and human development.

Description

The psychology of aging seeks to understand the regular changes in the organization of behavior and subjective experience that occur after young adulthood. Changes that occur earlier in life are typically categorized as development, with the differentiation of “development” and “aging” often popularly expressed through the metaphor of the hill of life. Historians note that with the rise of modernity, this metaphor of growth and decline replaced a circular view of human life that was expressed in religious iconography, showing the wheel of life from birth through death revolving around images of transcendence (Cole 1992).

Since the 1980s, psychologists have embraced a multidirectional model of aging, meaning that they view gains and losses as occurring throughout human life. Aging is commonly seen as a counterpart of development, with plasticity and opportunities for growth maintained throughout life, even as physical, psychological, and social losses accrue. These changes occur at different rates in different biopsychosocial

systems. Therefore, chronological age alone cannot be viewed as an explanatory variable.

The psychology of aging, which is sometimes called “geropsychology” or “psychogerontology,” emerged as a subdiscipline of psychology in the mid-twentieth century, although its roots reach back to ancient discourses on human longevity. Today, psychologists who study aging often collaborate with persons representing the many other fields that together form gerontology. These include scholars and researchers in the biomedical sciences, the social sciences, the arts, and the humanities, as well as practitioners such as nurses, social workers, neuro- and clinical psychologists, art and music therapists, and clergy.

The number of publications in the psychology of aging has increased exponentially in recent years. The 6th edition of the *Handbook of the Psychology of Aging* (Birren and Schaie 2006), published in 2006, illustrates the growth and diversity of this field. Like the previous volumes in this series of handbooks, chapters in this edition review earlier work and point out new developments in topics ranging from behavioral genetics to psychotherapy with older adults.

Although many people still hold negative views of aging and older adults, today there is greater emphasis in research and practice on healthy aging and resiliency. Researchers are documenting the ability of older persons to adapt to changing life circumstances, maintain positive affect, remain engaged with their communities, and cope with the stresses of late life, while practitioners are developing interventions to support older persons in making these adaptive responses.

Self-identification

Science

The psychology of aging primarily identifies itself as a science. Some research in the psychology of aging is barely distinguishable from biological research on topics ranging from gene expression to neural anatomy and function. Other research is situated within the social sciences. Regardless of

the focus of the research, the psychology of aging operates with the assumptions of modern science, including the necessity of ► **falsifiability** for hypotheses and theories.

Research designs vary according to the specific topics and populations being examined. For example, intervention studies of cognitive rehabilitation for memory impairment employ experimental designs with participants randomly assigned to treatment and control groups. Cross-sectional research compares persons of different ages and often analyzes effects of multiple predictor variables on various outcomes. Quite a few ongoing longitudinal studies throughout the world have contributed to the knowledge base about age change in psychological phenomena like speed of response, memory, intelligence, and personality. Occasionally, psychologists are interested in cohort differences and thus employ time-lag designs which compare cohorts on variables like grandparenting styles, attitudes about psychotherapy, and sexual behavior. Sequential designs enable psychologists to combine cross-sectional, longitudinal, and time-lag analyses in order to control for the varying effects of age, cohort, and time of measurement. One example of this type of research is found in ongoing analyses of data on primary mental abilities (i.e., aspects of intelligence studied through tests of verbal meaning, word fluency, number, spatial relations, memory, perceptual speed, and general reasoning), from the Seattle Longitudinal Study which began in 1956. These more complex designs enable psychologists of aging to explore both inter- and intraindividual change and stability in a variety of characteristics.

Psychologists who study aging also employ qualitative methods grounded in the human sciences, rather than the natural sciences. For example, interpretative phenomenological analysis is used to reveal the experiences of persons living with early-stage dementia. Interviews with aging persons, as well as narrative studies of their autobiographical writings, provide insight into the lived experience of old age in our time. Researchers continue to debate whether this type of work qualifies as scientific and whether

it meets the rigorous demands of science for reliability and validity of measures. Nevertheless, it has produced important insights into the phenomenology of old age experiences and has created a foundation for collaboration with artists, literary theorists, philosophers, theologians, and other scholars in the humanities.

Characteristics

One of the key distinguishing features of the psychology of aging is its awareness of time and the differential timing of biological, psychological, and social age changes. Although chronological age is a key index to time's passage, geropsychologists also must account for cohort differences and the effects of the historical period when data are collected. For example, current public awareness about the importance of a healthy diet for late life brain function may influence behaviors of older adults, making current research on diet and cognition hard to compare to studies conducted 20 years ago when there was less knowledge about diet and health.

Psychological research in general has mostly focused on young adults, especially those enrolled in the colleges and universities where research is conducted. Much of this research does not include a developmental perspective, and thus what we know about basic psychological phenomena like sensation and perception, attention, memory, learning, and problem solving is based upon observations of persons in their 20s. Much of this research implicitly assumes that as long as researchers control for variables like gender, education, race, and ethnicity, then observations can be assumed to have external validity. Geropsychologists also recognize the importance of controlling for the effects of demographic variables; in addition, however, they are aware that variable rates of change in biological, psychological, and social phenomena affecting aging persons produce increasing heterogeneity with increasing age. Thus, extra care must be taken in generalizing about research outcomes.

Because the psychology of aging is so intimately connected to gerontology, a broadly

interdisciplinary enterprise, geropsychologists tend to pay more attention than some psychologists to interconnections among genes, neurochemicals, brain systems, behaviors, perceptions and cognitions, personality traits, social relationships, and the cultural and historical contexts in which these are expressed. In particular, most psychologists of aging employ an ecological perspective to account for the dynamic, dialectical relationships between aging persons and their environments.

Finally, the psychology of aging examines a portion of the life cycle that is fraught with loss and inevitably closes with death. Intimations of loss and mortality elicit social stigma, adding to the burdens of old age. For these reasons, geropsychology engages more with existential issues of meaning and purpose than many other subdisciplines in psychology. This is illustrated in the growing literature on dementia that considers issues of self and identity as memory fades. Other areas of geropsychology that acknowledge existential issues include studies of terminal care, coping and resiliency, civic engagement, and late life religiousness and spirituality.

Relevance to Science and Religion

In general, psychologists of aging do not participate in contemporary debates about the competing truth claims of science and religion. Gerontologists have been conducting research on religion, spirituality, and aging since the 1980s (although some sociologists of religion studied older adults many decades earlier). This work has primarily addressed connections between religious beliefs and practices and the health of older persons (Koenig et al. 2001). In the 1990s, some researchers expressed concern that such studies harmed the tenure aspirations of persons in academia, but by the turn of the twenty-first century, enough studies had been published in respected journals to reduce that concern somewhat. In addition, funding from the federal government, as well as private foundations, became available for research on the relation of religion and health. This supported investigations

into what some psychologists called the “mechanics,” underlying the observed salutary effects of religious activities and beliefs. However, with the exception of a few persons working in the area of “critical psychology” or “critical gerontology,” scholarly study of the interface between science and religion is lacking.

Sources of Authority

Authority in the psychology of aging derives from systematic, repeatable observations that have been reviewed by peers and published in respected journals (usually those with high rejection rates). Longitudinal studies are accorded special respect, particularly if they include multiple cohorts, allowing for complex analyses and control for age, period, and time of measurement effects. Interventions tested with randomized, controlled trials are also highly respected. The psychology of aging tends to locate authority in the most recently published papers with the exception of highly cited “classic” papers by certain leading researchers.

The first generation of geropsychologists began their work in the 1950s and flourished in research universities in the second half of the twentieth century. Included among these elder “sources of authority” in geropsychology are Paul B. Baltes, James E. Birren, Irene M. Hulicka, Robert Kastenbaum, M. Powell Lawton, K. Warner Schaie, Lillian Troll, and Sherry Willis (Birren and Schroots 2000). By the turn of the twenty-first century, some had retired or died. However, others have continued to contribute to the field in the years following their first retirements, thus demonstrating the vitality of what some call the “third age” of life (the time between the first retirement and disability or death).

Ethical Principles

Research on the psychology of age (cross-sectional designs), older adults (descriptive and experimental designs), cohorts (time-lag

designs), and aging (longitudinal designs) must abide by the *Ethical Principles of Psychologists and Code of Conduct* of the American Psychological Association (APA). The APA Ethics Committee regularly meets to review violations of the code of conduct and recommend changes necessitated by evolving technology, forms of psychological interventions, and research protocols. Researchers must be competent to conduct the research, obtain informed consent from participants, and guard the confidentiality of participants’ responses. Research protocols must be approved by institutional review boards (IRBs) which usually consist of peers in the field as well as informed citizens and representatives of the institution where the research is to be conducted.

Some psychologists of aging provide various kinds of services to older adults, including cognitive rehabilitation and psychotherapy. They must also abide by the *Ethical Principles of Psychologists and Code of Conduct*, be competent practitioners, obtain informed consent, and insure confidentiality. Interventions must be evidence-based, meaning that they have been tested scientifically, preferably in randomized controlled trials. In addition to the *Ethical Principles of Psychologists and Code of Conduct*, the APA has also published guidelines for practice with older adults. This document details particular concerns that may arise in working with older persons, including questions about mental competency (Abeles et al. 1998). Researchers and practitioners working with persons along the dementia spectrum must carefully assess participants’ competence to provide informed consent. The Capacity to Consent to Treatment Instrument (CCTI) is one example of an assessment tool designed for and tested with older adults (Marson and Hebert 2006). If a person is incapable of providing consent, then it must be obtained from the legal guardian.

Key Values

As stated in the first issue of the *Journal of Gerontology* (1946) published by the newly formed Gerontological Society of America

(GSA), geropsychologists and other researchers and practitioners in gerontology seek to add life to years in a time when advances in medicine have added years to life. This goal continues to be central to gerontological research and practice. The GSA's mission statement adds that gerontologists promote and engage in multi- and interdisciplinary research that is widely disseminated to practitioners and political decision makers. Similarly, the American Society on Aging (ASA) states that its membership works to advance knowledge and skills that will lead to increased quality of life for older persons.

Psychologists of aging value the acquisition of scientific knowledge and the translation of that knowledge into practice. They employ a biopsychosocial approach to understanding older persons, including those with neurological impairments. While the biomedical interpretive framework regards older persons primarily in terms of their physical deficiencies, geropsychologists insist on considering the complex interconnections among physical conditions, psychological resources, past experiences, relationships, and cultural and historical contexts. This approach embraces what geropsychologist Paul Baltes called a "multidirectional" view of life span development, meaning that gains and losses coexist. Thus, an aged person might show multiple losses of physical functionality while at the same time demonstrating gains in effective coping strategies, meaningful relationships, and spiritual insight.

Increasingly, scholars in gerontology are critiquing traditional Enlightenment values of rationality and individualism. Those who work with persons with dementia are especially aware of the stigma these values attach to persons living with memory loss and cognitive confusion. Emphasis on personhood, as formed and rooted in relationality, has produced a new culture of dementia care and has inspired research on the lived experience of dementia (Kitwood 1997). The emerging discussion of relationality among geropsychologists has broadened views on older adults' spirituality, including persons living with dementia (Allen and Coleman 2006), and has invited dialogue with theologians.

Conceptualization

Nature/World

The psychology of aging conceptualizes nature/world objectively as matter that exists in space and time and subjectively as the felt experiences of older persons. The dialectical perspective on aging and development argues for the reciprocity between human actions and the world such that people influence their environments and environments influence persons. This occurs at multiple levels of analysis, from the genetic to the social. Geropsychologists generally accept the competence-press model first articulated by M. Powell Lawton, which argues that subjective well-being and adaptive behaviors are a function of the interaction of individuals' competencies and environmental challenges.

Human Being

A human being is a person, formed from birth until death through the interplay among individual characteristics, relationships with others, and the environment (both human created and natural).

Life and Death

Psychologists of aging accept evolutionary biology's perspective on the origins of life. They are more concerned with the ways death is defined biologically, psychologically, and socially. They attempt to counter the popular conception of the state of advanced dementia as akin to psychological death (e.g., the death of the self), a position that often leads to social death whereby others treat the individual as if he or she is already dead. This produces what Tom Kitwood (1997) calls a "malignant social environment" that elicits problematic behaviors.

Some geropsychologists conduct research on psychosocial conditions associated with morbidity and mortality. These include anxiety, depression, and social isolation. Some research has shown that religiousness functions as a stress buffer for older persons and is associated with better health and longer life. Geropsychologists also study predictors of mortality in aged persons, such as declines in measured intelligence and

changes in personality traits in the 6 months preceding death. Finally, clinical geropsychologists sometimes work with bereaved persons and with individuals in hospice care as they prepare for death (Oyebode 2008).

Reality

Most psychologists of aging do not debate the nature of reality and view it as what is presented through various stimuli that affect sense organs. In other words, psychology takes an empirical approach to understanding reality. However, under the influence of postmodern critical theory, some geropsychologists emphasize internal and external influences on the ways human beings interpret information. Gender, race and ethnicity, social class, culture, and language, as well as physical and mental health and well-being, are all seen by these persons as shaping older persons' understanding of reality.

Knowledge

The psychology of aging follows an empirical epistemology, meaning that reproducible observations are viewed as the source of knowledge. It should be noted, however, that geropsychologists who are open to the humanistic stirrings in gerontology are willing to entertain the idea that metaphor as expressed in the arts, literature, and religion yields another pathway to knowledge about aging and older people's experiences.

Truth

Truth in science is viewed as partial. All scientific assumptions must be subjected to procedures that have the potential to prove the assumptions to be false. What is held as true today may be refuted tomorrow by additional evidence. Psychologists do not debate the meaning of ultimate truth. When psychologists of aging study the religiousness of older adults, they do not evaluate the truth of the religious convictions held by elders; rather, they describe the effects of religious convictions on behavior and physical and mental well-being.

Perception

Perception refers to the organization and interpretation of information received from the

senses. Perception is viewed as being shaped by sensory acuity, by individual motivations and emotions, and by socially reinforced attitudes.

Psychologists of aging study various forms of perception. For example, they inquire about how younger persons' perceptions of older people are informed by social stereotypes. Another example is found in research on how changes in auditory sensation, the speed of neural conduction, and information processing in the brain affect older people's ability to perceive speech.

Time

Psychologists of aging differentiate physical time (measured by clocks and calendars), biological time (expressed in circadian and metabolic rhythms), psychological time (experienced subjectively as duration of present events, memory of the past, and anticipation of the future), and social time (normative expectations about the timing of important life events). Currently, a dominant geropsychological theory – socioemotional selectivity theory – emphasizes older people's sense of time passing and their awareness that the duration of their lives is limited. This awareness of the limitations of personal time influences them to select social partners with whom they feel most comfortable and from whom they receive support for positive affect.

In addition to conducting research on perceptions of time by older adults, geropsychologists are also interested in timing in terms of the speed with which the nervous system processes information. A robust observation in gerontology is that aging persons experience generalized slowing of neural transmission, a condition that affects multiple psychological systems including sensation, attention, and cognition.

Time is also important to geropsychologists in terms of how they design their research. For example, it is important for them to be aware of the confounding of age and time of measurement in a simple longitudinal design. This means that if the same persons are tested periodically over a period of years, the researcher cannot know if differences are due to increasing age or the circumstances of the time when the observations were gathered. Similarly, cohort

and time of measurement are confounded in simple time-lag designs.

Geropsychologists interested in older adults' religiousness and spirituality have noted that the experiences of aging often produce a greater appreciation of the meaning of time. This may be expressed through the practice of spiritual disciplines like meditation and a deeper appreciation of how religious rituals order time (McFadden and Atchley 2001).

Consciousness

Although psychologists have debated the nature of consciousness and its neurophysiological substrate since the founding of the discipline, psychologists of aging tend to focus more on subjective awareness which is sometimes called "autonoetic awareness." This name was given to the feeling of remembering one's own past experiences by the well-known cognitive psychologist, Endel Tulving. A more common term is episodic memory. Humans have the ability to engage in imaginative time-travel that can be personal, in terms of recalling one's past, and historical, as when people picture themselves living in former times. Autobiographical memory consists of narratives, or stories, about one's life. Researchers have found that in old age, the greatest number of autobiographical memories originated between ages 10 and 30, a phenomenon sometimes called the "reminiscence bump."

People also are aware of the things they know. As Tulving said, they have a feeling of knowing about "facts" about the world, including their own grasp of languages and knowing what words mean in different tongues. Tulving called this semantic memory. Sometimes the feeling is frustratingly incomplete, as when people describe the "tip of the tongue" phenomenon when they can grasp only partial knowledge about a word (e.g., number of syllables) or world fact (e.g., recalling that a city is in the northeast part of a country without being able to recall the city's name). The cognitive psychology of aging examines how episodic and semantic memories are preserved as people age, with

most research finding more robust maintenance of semantic memories.

In addition to differentiating episodic and semantic memory, psychologists of aging also differentiate explicit from implicit memory. Explicit memories are those that persons are aware of (or conscious of) recalling. Implicit memory is nonconscious, with no perceptible effort involved. Getting on a bicycle and riding it is an example of procedural, implicit memory. Those who work with persons living with dementia often observe implicit memory. For example, you might ask a person with dementia to recall the first line of Psalm 23 and receive no response. However, in a worship setting, even those who rarely if ever speak sometimes repeat this well-learned Psalm when the worship leader begins reciting it.

In the laboratory, psychologists sometimes use a method called "priming" in which they activate ideas implicitly and then observe how these implicit, nonconscious ideas affect behavior. For example, one group of elders might be asked to write a paragraph about how they envision their deaths. Another group might be asked to write about how they envision having a tooth drilled. Terror management theory predicts that the group that was "primed" with death thoughts will behave differently than those "primed" with pain thoughts, with the former group more inclined to protect their self-esteem and views of the world when asked to do a task like reading a paragraph about a crime and deciding on a punishment. Priming has also been used in studies of religiousness; when God concepts are implicitly activated, people show greater helpfulness to others.

Rationality/Reason

Psychologists of aging study reasoning capacity and style in older adults. Much research focuses on everyday problem solving as a way of preserving ecological validity in data collection and promoting greater generalization of findings beyond the research environment. In this work, older persons may be asked to respond to short vignettes by telling what they would do if, for example, they discovered that the electricity had gone off in the night. Scores on the task reflect the number of safe

and effective solutions to the problems posed. Sometimes these problems are practical, like electricity failure, and some are interpersonal, as, for example, when an elder is asked about advice she would give to a young pregnant granddaughter. Many researchers have noted that, compared to younger adults, older people tend to combine emotional coping strategies for managing feelings with practical behavioral solutions. In other words, they show an integration of reason and emotion.

Longitudinal studies show a gradual decline in inductive reasoning abilities with age. However, the Seattle Longitudinal Study, which includes a number of different birth cohorts, has demonstrated an increase in inductive reasoning ability in birth cohorts since the 1920s, which is probably due to greater educational emphasis on problem solving rather than rote memorization.

Since the Enlightenment, philosophers and psychologists have emphasized the primacy of reason over emotion, with rationality often cited as the defining characteristic of being human. This position, however, has been challenged by researchers whose work on the interface between reason and affect has demonstrated that without feeling, human beings cannot make good judgments. Moreover, the preeminence of reason in defining what it means to be human is also challenged by persons living with the progressive memory loss and confusion of dementia. Although they may no longer be able to reason about problems as they once did, they continue to express emotion, demonstrate agency, and respond to persons and things in their environments. An emerging new culture of dementia care locates personhood in relationships and not in individual reasoning abilities (Kitwood 1997).

Mystery

In the empirical psychology of aging, the closest researchers come to the notion of mystery is in their research on wisdom. Nearly all writing and research on wisdom in the last two decades has emphasized that one important characteristic of wisdom is the acknowledgment of the uncertainty of life. Thus, elders described as wise often say that aging has given them a greater appreciation for mystery.

Sometimes the felt sense of mystery merges with the experience of the holy. This need not be occasioned by religious rituals or settings. Gazing into the eyes of one's first grandchild, contemplating the twists and turns of life's journey, watching a strapping teen grandson fishing in the lake by the family cottage, and sitting at the bedside of a beloved spouse slipping into death – all these and many other experiences may envelop elders in a sense of mystery that some call holy.

Relevant Themes

1. Although psychologists of aging have begun to study late life religiousness and spirituality, much more work remains to be done, particularly in terms of exploring how elders experience spiritual development. They may not associate this development with the beliefs and practices of the world's religions, and in fact, studies of the baby boom cohort (born between 1946 and 1964) suggest that they will not engage with religious ideas and experiences in traditional ways as they grow older. As neuroscientific findings about the aging brain accumulate, there will be a greater need for scholarship that brings science and religion into dialogue about aging persons' experiences of all of the topics addressed above, especially time, consciousness, and mystery.
2. The scientist-practitioner model of geropsychology demands scientific evidence regarding the efficacy of activities undertaken to improve the welfare and well-being of older persons. Pastors and others who offer spiritual care to older persons generally do not subscribe to this model. Nevertheless, their work can comfort the bereaved, support those seeking forgiveness, challenge the complacent, and give hope to the despairing. Should these professionals submit their practices to the scrutiny of science? These are discussions that need to be conducted within an atmosphere of mutual respect between those representing sciences and those representing religions.

Alchemy in Islam

Sébastien Moureau

FNRS, Institut Orientaliste, Université
Catholique de Louvain (UCL), Louvain-la-
Neuve, Belgium

Related Terms

[History of chemistry in Islam](#); [Islamic alchemy](#)

Description

Alchemy is, in the strictest sense, an attempt at finding a process to transmute vile metals (such as lead and copper) into gold or silver. It was transmitted from Greece to the Arab world (probably through Syriac intermediaries) during the ninth century for the most part (even if some treatises had perhaps already been translated some time before). Alchemy appears as a discipline in its own right in various Islamic classifications of sciences, such as that of al-Fārābī. The subsequent development of alchemy in Islam was significant, and it is from the Latin translation of Arabic works that the medieval West owes to know of alchemy. Many trends in the Arab-Muslim science of alchemy can be traced back, ranging from purely metallurgical details to properly Gnostic or magic elements.

Unfortunately, the discipline as such has not been much studied up to now, and only some treatises have been edited.

Self-Identification

Science

Alchemy may be called a science in its modern acceptance especially when it is considered in its link to metallurgy: some classifications of materials, some practical operations, etc.

In the context of medieval Islamic thought, alchemy is a science of its own, since it is part and parcel of theoretical knowledge.

Transmutation was the subject of important debates and controversies during the Middle Ages of Islam. Some scholars, like Avicenna, denied the possibility of transmutation and were interested only in the very practical processes (such as dyeing metals).

Religion

Alchemy cannot be defined as a religion. It would be more relevant to underline the links it has with religion, as is often the case with Gnostic views. But some alchemists did mix up Islamic religion with alchemy to such a degree that religion may be considered the principle of their thought (see below).

Characteristics

The specific feature of alchemy is its attempt to find a process to transmute vile metals into gold or silver.

Relevance to Science and Religion

Many links between alchemy and religions can be traced back. For some alchemists, alchemy could be viewed as a purely religious fact. For instance, by mixing shī'ite interpretations with alchemy, many texts of the Jābirian corpus (see below) draw connections between man, world, and alchemical work. According to them, the alchemist, by transmuting lead into gold, is simultaneously purifying himself and leading his soul to God.

Sources of Authority

Two alchemists are representative of the two major trends in Islamic alchemy (this division is exaggerated here, all alchemists are mixing

different considerations, and it is difficult to classify them in so distinctive types). The religious point of view can be represented by many texts attributed to Jābir ibn Hayyān (a pseudographic corpus probably written in the ninth century, but the dating and attribution are subject to controversy). The other trend, based on more technical and empirical considerations, is represented by the work of Abū Bakr Muḥammad ibn Zakariyyā' al-Rāzī (865–925), the well-known philosopher. We may also mention the *Emerald tablet*, a very short text of Greek origin (contained in the *Kitāb sirr al-khalīqa* of Bālīnūs (pseudo-Apollonius of Tyana)), and Muhammad Ibn Umayl (first half of the tenth century), representing a more allegorical trend.

Key Values

In the scientific and practical trend of alchemy, the key values are accurate observation and experiment.

As for the religious trend, initiation (reception of the intellect) is the main principle, but, experiment has also a very important place (depending on the author).

Conceptualization

Nature/World

Object of the alchemical work and knowledge.

Human Being

In the scientific and practical trend, human being (i.e., the alchemist himself) is the subject of the alchemical work.

But in the religious trend, the alchemist is not only the of the alchemical work, but also its subject and object.

Reality

Cf. truth.

Knowledge

In the scientific and practical trend, knowledge is considered as theoretical and practical understanding of nature.

In the religious trend, knowledge is a revealed understanding of nature and man (i.e., result of a gift).

Truth

What is in accordance with nature. In Arabic, the word *ḥaqq* (truth) has an epistemological and ontological meaning: it does not only mean “truth”, but also “reality”.

Perception

Foundation of the alchemical knowledge, especially in the Aristotelian conception of knowledge acquisition (the neoplatonist trend basing the knowledge on divine illumination).

Mystery

In the religious trend, the alchemical work is considered a mystery, whose knowledge is given by God (via the prophet or the imām).

Algebra in Islam

Jeffrey A. Oaks

Department of Mathematics and Computer Science, University of Indianapolis, Indianapolis, IN, USA

Description

Algebra is the only medieval numerical problem-solving method capable of resolving general quadratic problems (those involving the square of the unknown). The first written algebra books were lifted from the oral tradition in the early ninth century. Al-Khwārizmī, Ibn Turk, and Sanad ibn ‘Alī are all known to have composed books on algebra during the reign of al-Ma’mūn (813–833), though only al-Khwārizmī’s seminal *Book of Algebra* survives complete. In addition to books devoted to the method, algebra is also explained in chapters of many arithmetic textbooks.

The presentation of algebra is usually divided into two parts. First comes an explanation of the names of the powers, the six simplified equations and their solutions, and the rules for operating on polynomials and roots. This is followed by a collection of worked-out problems which illustrate the method. All texts were written out entirely in words, though some later texts use Hindī numerals.

There are three basic stages in the algebraic solution to a problem:

Stage 1: An unknown quantity is named (usually as a “thing”), and an equation is set up.

Stage 2: The equation is simplified to one of six canonical types.

Stage 3: The proper procedure is applied to arrive at the answer.

The first degree unknown, our x , is most often called *shay’* (“thing”), and sometimes *jidhr* (“root”). The second power, our x^2 , is called *māl* (“sum of money/property/wealth”). Units were counted in dirhams, a denomination of silver coin, or simply “in number.” So al-Khwārizmī’s equation “a hundred ten and two *māls* less twenty-two things equals fifty-four dirhams” corresponds to our $110 + 2x^2 - 22x = 54$.

The Arabic name of algebra, *al-jabr wa’l-muqābala*, literally means “restoration and confrontation,” the two fundamental steps of stage 2. For example, to simplify the equation “four things equal ten less a thing” ($4x = 10 - x$) Abū Kāmil must “restore” the ten, which has been diminished by a “thing”: “So restore (*ajbir*, conjugated from *al-jabr*) the ten by the thing, and add it to the four things. So it yields: five things equals ten dirhams” ($5x = 10$). Like terms on opposite sides of an equation are “confronted,” resulting in their difference on the side of the larger. To simplify the equation “a *māl* and four things equals five things and thirty dirhams” ($x^2 + 4x = 5x + 30$) Ibn al-Bannā’ writes “So you confront (*tuqābil*, from *al-muqābala*), so there remains [after the subtraction] a *māl* equals a thing and thirty dirhams” ($x^2 = x + 30$) (Oaks and Alkhateeb 2007).

At the end of stage 2 an equation of first or second degree has been simplified to one of these six forms:

Simple equations

1. *Māls* equal roots (in modern terms, $ax^2 = bx$)
2. *Māls* equal numbers ($ax^2 = c$)
3. Roots equal numbers ($bx = c$)

Composite equations

4. *Māls* and roots equal numbers ($ax^2 + bx = c$)
5. *Māls* and numbers equal roots ($ax^2 + c = bx$)
6. *Māls* equal roots and numbers ($ax^2 = bx + c$)

Medieval algebraists worked with six equations instead of our single $ax^2 + bx + c = 0$ because the algorithms for their solutions take

the numbers (coefficients) of the individual terms as parameters, and these must be positive.

There is a particular numerical recipe for solving each of the six types. Most books show the solutions in terms of specific examples, like al-Khwārizmī's solution to the sample type 4 equation "a half *māl* and five roots equal twenty-eight dirhams" ($\frac{1}{2}x^2 + 5x = 28$):

So you want to complete your *māl*, so that it becomes whole, which is that you double it. So double it and double everything you have which is equated with it. So it yields: a *māl* and ten roots equals 56 dirhams. So halve the (number of) roots, so it yields five. Multiply it by itself, so it yields 25. Add it to the 56, so it yields 81. Take its (square) root, which is nine. Subtract from it half the [number of] roots, which is five. There remains four, which is the root of the *māl* that you wanted, and the *māl* is sixteen and its half is eight (al-Khwārizmī 2009, 103 (my translation)).

Worked-out arithmetic problems often occupy more pages than the explanation of the rules. The enunciation of a typical problem from Abū Kāmil's latter ninth century *Book of Algebra*, is: "Ten: you divided it into two parts. So you divide the larger by the smaller. Then you add what results from the division to the ten. Then you multiply what results by the larger part, so it yields sixty-nine dirhams." Abū Kāmil begins the solution "Its rule is that you make the smaller part a thing." He then works out the operations outlined in the enunciation in terms of this "thing" to arrive at the equation "nine-tenths of a *māl* less two things and a tenth of a thing equals ten less a thing" ($\frac{9}{10}x^2 - 2\frac{1}{10}x = 10 - x$). This equation is then simplified to a type 6 equation and solved.

Algebra was used to solve textbook problems in branches of mathematics beyond arithmetic. By expressing lengths and weights as numbers, problems in geometry and metrology were also solved by setting up and solving an equation.

There are several aspects of the method of algebra which attracted the interest of mathematicians. Already in al-Khwārizmī's book the solutions to the composite equations and the method of adding polynomials with diminished terms were proven by geometry using lettered diagrams. These proofs were made rigorous

with explicit references to propositions from Euclid's *Elements* by Thābit ibn Qurra and Abū Kāmil later in the ninth century. Powers greater than the *māl* were introduced in Qusṭā ibn Lūqā's translation of Diophantus' *Arithmetica*, ca. 860. The third power is *ka'b* ("cube") and higher powers are written as combinations of *māl* and *ka'b*. In the early eleventh century the arithmetic of polynomials was expanded and explored by al-Karajī. Probably following Diophantus, he extended the range of powers to include their reciprocals (our negative exponents), and he applied the numerical method of root extraction to polynomial equations. His work was further developed in the twelfth century by al-Samaw'al.

Indeterminate analysis was part of Arabic algebra from the beginning. Many inheritance problems in al-Khwārizmī's book are indeterminate, and Abū Kāmil devoted an entire book to abstract indeterminate analysis without being aware that Qusṭā had recently translated Diophantus' Greek into the vocabulary of contemporary Arabic algebra (Djebbar 2005).

Geometers found in algebra a tool for problems not solvable by ruler and compass. In the latter ninth century al-Māhānī converted a problem of Archimedes into a cubic equation which he unfortunately could not solve. In the following century, Abū Ja'far al-Khāzinī reinterpreted the unknown "thing" in the equation as a line and transformed it back into a geometry problem. This way he was able to represent the solution by a segment extending to the intersection of two conic sections.

This potential for algebra to serve geometry inspired al-Khayyām (Omar Khayyam, 1048–1131) to write his *Treatise on the Proofs of Problems in Algebra*. In addition to numerical solutions, he gave geometric constructions for solving the 25 simplified equations of degree three or less. In his proofs of these solutions he reinterpreted the homogeneous unknowns *shay'*, *māl*, and *ka'b* as geometric magnitudes of degree 1, 2, and 3, respectively. Sharaf al-Dīn al-Ṭūsī (d. 1213) furthered al-Khayyām's work by specifying conditions on the coefficients which determine the number of solutions, and by providing algorithms for finding numerical solutions (Oaks 2011).

No work in this “geometric algebra” is known after al- Tūsī’s, but production of practical books and chapters on numerical algebra (usually without the geometric proofs) continued to be written down to the nineteenth century.

By the twelfth century an interesting notation had developed in the Maghreb in combination with Hindi numerals for working out problems by algebra (Abdeljaouad 2002). In some respects it is more symbolic than the notation of Italian abacus authors.

Algebra was sometimes invoked to solve problems in other branches of mathematics. In addition to the application of algebra to geometry in Archimedes’ problem, al-Māhānī (and others) also presented an arithmetical reinterpretation Book X of Euclid’s *Elements*, on the theory of commensurable and incommensurable magnitudes. Via algebra they found, for instance, that $\sqrt{9 - \sqrt{45}} = \sqrt{7\frac{1}{2}} - \sqrt{1\frac{1}{2}}$. Later, al-Khayyām solved problems in specific gravity using algebra, and al-Fārisī used algebra to manipulate prime numbers in Thābit’s formulas for amicable numbers. In the early fifteenth century al-Kāshī set up a cubic equation whose solution is the sine of 1° , and which he solved by a method equivalent to the Ruffini-Horner method.

Algorithm

Linda Sherrell

Department of Computer Science,

The University of Memphis, Memphis, TN, USA

An algorithm, which is usually expressed in natural language or pseudo-code, is a step-by-step procedure to solve a problem. Pseudo-code is a mixture of words from the programmer’s natural language and constructs (similar or actual) from the target programming language. Note that a programmer should construct his or her algorithm before composing the actual code for the program.

Description

A computer algorithm is a computational procedure that describes how to perform a series of discrete steps to achieve a particular task and obtain a solution to a computational problem, such as sorting a bunch on integers in increasing order. Algorithms are described visually as *flow-charts* or textually in a natural language as *pseudocode*. A given algorithm is usually intended to be run by a digital computer, in which case it must be translated (or implemented) into a piece of software in a programming language, and is thus often confused with a “program,” especially when it is described in pseudocode closely resembling a programming language. Sometimes, the term “software” is used to refer to one or several programs that perform one or several related tasks (see “► [Software Engineering](#)”).

An algorithm consists typically of control structures and data structures. Control structures include *conditionals*, which allow instructions to be carried out in different logical conditions, and *loops*, which allow the same instructions to be repeated several times with slightly different effects. Data structures store data as they are being manipulated during the execution of an algorithm. Data structures can be quite complex and are designed to support specified types of operations efficiently. The word “algorithm” is a latin transliteration of the Persian mathematician’s family name *al-Khwārizmī*, to whom the origin of the most basic data structure (the decimal notational system) and algorithms (to solve linear and quadratic algebraic equations) can be traced in the 800 s A.D.

An algorithm can be described either abstractly and informally in a natural language or technically and formally at a lower-level machine language. In any case, an algorithm needs to be precise and unambiguous. Two essential attributes of an algorithm are *correctness* and *efficiency*. Although an acceptable algorithm must produce correct results for the problem it is intended to solve, recent advances on *probabilistic* or *randomized* algorithms focus on algorithms as strategies that are provably mostly correct, although they may

produce erroneous answers or none at all (but with low probability). In general, it may be very hard to establish the correctness of an algorithm. This is one reason why software is often buggy and in need of updates. Another essential attribute of an algorithm is its efficiency, i.e., how fast it will run on any computer, particularly as the size of the input data increases. Since an algorithm can be slow on one computer and fast on a more powerful one, the efficiency of an algorithm is formally defined as an *asymptotic intrinsic measure of the order of growth of the running time as a function of the size of the inputs* (e.g., the number of integers to be sorted), and not in absolute units. Asymptotic complexity allows efficiency of algorithms to be assessed consistently and independently of the underlying computer they may be eventually run on. Based on these measurements, algorithms are considered tractable if they can run in a time that only increases polynomially as functions of input size (e.g., linearly or at quadratic rate for quicksort). Many important problems in real-world applications (such as the Traveling Salesperson problem) are not known to be solvable efficiently by polynomial-time deterministic algorithms on conventional computers. Whether such solutions exist is considered one of the most important open problems in computer science and is known as the $P = ?NP$ question.

Researchers in this area have discovered that concepts from biological evolution can also be used as an inspiring strategy to develop so-called *genetic* and *evolutionary* algorithms, which are often used to optimize specific objectives (known as fitness functions, for example, the number of times a solution in the pool correctly sorts a number of inputs from a given number of cases). Using evolutionary strategies, these algorithms start with a population (pool) of approximate or imperfect solutions, which are then improved using *mutation* and *crossover* operators to generate better and better solutions through rounds of an “evolve-evaluate” cycle (Mitchell 1998). It is well known, albeit surprising, that after hundreds of such iterations, these algorithms usually and eventually converge to good solutions with very high performance scores. Further, some argue that these features should

be an integral component of every computational procedure (Garzon 2012).

Self-identification

The area of design and analysis of algorithms is definitely part of computer science. The efficiency of an algorithm is well defined and can be measured. Correctness of algorithms can be proven and tested. Repeatability is an essential feature of the study of algorithms. Published algorithms can typically be implemented and tested in most programming languages.

Characteristics

Algorithms are at the heart of computer science and increasingly of other sciences. The concept of “computational thinking” is spreading to many other areas of science in order to carry out complex tasks for which scientists increasingly rely on computers, and so scientists must describe their strategies in an algorithmic form.

Relevance to Science and Religion

Here, entries also may address practical implications the area “Science and Religion” may have for, for example, the teaching of a particular discipline, the career of the scientists/nonscientist, and the place of that discipline within a university/academic setting and in society.

There is no such interest among practitioners or theorists in this field.

Sources of Authority

For example, very recent journal articles (i.e., recent is more valuable), books, ancient manuscripts, a particular written text, a particular person, or influential figure (e.g., in the case of some religions/traditions, Elders, the Pope, or the Dalai Lama; in the case of some sciences, perhaps Newton, Einstein, etc).

There are many books, conferences, and journals focusing on the design and analysis of algorithms. Sources of authority in this area include (Cormen et al. 2009; Skiena 2008; The Art of Computer Programming 1998; Mitchell 1998; Garey and Johnson 1979).

Ethical Principles

Computers can be instructed to do good as well as evil. Certain algorithms can take the form of computer viruses, which are programs with unethical agendas. The programs exploit vulnerabilities in computer systems programs to steal private information and use them for unexpected purposes. Producing and/or using these algorithms is considered unethical and it is in fact unlawful in most countries.

Key Values

Computer science and technology have made significant advances in the past two decades due to breakthroughs in both hardware and software. The area of algorithms provides the framework, techniques, and processes for designing and analyzing complex software. As computer science keeps permeating the fabric of society, the role of algorithms and software remains essential.

Conceptualization

Natural/World

Algorithmic researchers continually borrow ideas from the natural world, including evolution (genetic algorithms), how ants form colonies (ant colony optimization), how birds fly in formation (swarm optimization), or how metals cool (simulated annealing).

Human Being

There are certain algorithmic strategies, especially in the area of Artificial Intelligence, aiming to simulate human behaviors, such as,

deduction, learning, languages, vision, and tact. The goals of these lines of research are twofold. By mimicking human behaviors, scientists aim to produce software embedded in robots and other structures that are effective at using these processes to perform tasks that ordinarily only humans could perform (such as playing chess, participating in games such as jeopardy, doing the dishes, or driving a car). Conversely, such studies help better understand human behaviors.

Rationality/Reason

The design and analysis of algorithms are based on reasoning.

Reality

Although not directly applicable, algorithms running on computer programs can control physical reality in very direct ways (such as automatic pilots to fly airplanes, controls for nuclear power plants, software to trade in the stock market, implants in humans to control prostheses, or cochlear implants to help people cope with disabilities).

Knowledge/Truth

The correctness of algorithms is based on mathematical truth in a model of objective reality.

Time

Efficiency is measured as running time and is usually conceptualized as the value of a counter (digital clock) on an electronic computer. Some problems require algorithms that may take billions of years to run and are not considered feasible or efficient.

Relevant Themes

Implementable algorithms are deterministic. Nondeterministic procedures are possibly beyond the capability of conventional computers, although quantum computers may be capable of running them (see “► [Quantum Computing](#)”).

[God; Modernity in Buddhism and in Islam](#)

Description

Allah, an Arabic word, means God, in the monotheistic sense. Allah is the center of the Qur'an

and Islam, as is reflected in the Islamic testament of faith, “There is no God but Allah.” He is *Rabb al-Alamin*, Lord of all Worlds – human, animals, the earth, the universe, angels, this world, and the next. He is the Creator of everything, the Provider, who gives life and death, and the ultimate Judge.

When looking to discuss the characteristics of Allah, the main source must be the Qur’an, Allah’s message to humanity, in which His characteristics are outlined. The picture the Qur’an gives of Allah appears to offer a fine balance of attributes: Allah is both before and after everything, the first and the last; manifest in His visible creation but also beyond sight: “*No vision can take Him in but He takes in all vision. He is the All Subtle, the All Aware*” (6:103), merciful and loving and turns towards those who repent, though His punishment is severe (40:3). When everything else disappears, “*all that remains is the Face of your Lord, full of majesty and bestowing honour*” (55:27). Allah transcends everything but observes everything, gives provision to every creature, and knows where each one is at any moment (11:6). He encompasses everything. He is closer to people than their jugular veins (50:16). He sends revelation for their guidance and every individual will stand before Him for judgment.

A crucial attribute is Allah’s Oneness (*tawhiid*). He has no child or equal or partner. Indeed the whole discipline of Theology in Islam is called the Science of Tawhiid. The Qur’an argues this concept repeatedly: “*If there had been in the heavens and the earth any god other than Him they would have fallen into ruin*” (21:22) “*each would have tried to overthrow the others*” (23:91); He is the One God of all. He is described in the Qur’an as the eternal Reality (*al-Haqq*). Everything else in creation is ephemeral, like plants that flourish then wither and disappear. Allah’s laws in the universe are unchangeable (35:47). *Al-Haqq* also means the Truth: “*If the truth were in accordance with their desires, the heavens, the earth and everything in them would disintegrate*” (23:71).

All these qualities and others mentioned in the Qur’an to describe Allah are summarized in the

well-known list of His 99 Beautiful Names. Muslims memorize and chant these, inscribe them on plaques, posters, and other public and private objects, to contemplate them and inspire themselves and others to emulate these qualities. Some of the attributes of Allah were debated at length, particularly from the time when the Muslim world expanded and came into contact with Greek philosophy and generations of Muslim philosophers tried to reconcile these attributes with the ideas of philosophers like Aristotle. The debate continued for centuries, culminating in a work written by Ibn Rushd (Averroes) (d. 1198 AD) known in English as *The Harmony of Religion and Philosophy*. In his Introduction, he says:

All that is wanted in an enquiry into philosophical reasoning has already been perfectly examined by the Ancients. All that is required of us is that we should go back to their books and see what they have said in this connection. If what they say be true, we should accept it and if there be something wrong, we should be warned by it. Thus, when we have finished this kind of research we shall have acquired instruments by which we can observe the universe and consider its general character.

As Ibn Rushd also notes, theological discussion has many characteristics of philosophical discourse. The Qur’an is an argumentative and rational text. From beginning to end, it provides arguments for all its beliefs and teachings. Nothing is assumed, even the existence of God. The Qur’an asks its audience to think on the nature of the Divine, posing the question for the disbelievers, “*Were they created out of nothing? Did they create themselves? Did they create the heavens and the earth?*” (Qur’an 52:35–36). The universe itself is presented as signs (*aayaat*) that prove the existence of a Creator and caring Lord. The word *aayaat* (sing. *aaya*) appears in the Qur’an 382 times, and it is through these signs that Allah makes Himself known, “*We shall show them Our signs everywhere and in themselves until it becomes clear to them that this is the Truth.*” (Q.41:53). The Qur’an urges people to observe, think, and find out about Allah’s laws in the universe; it then urges them to look as hard as they can at what is around them until they can look no more (67:7). They are even challenged to

“penetrate the heavens and the earth” if they can (55:33). The more they know, the more they will appreciate Allah, “*It is those of His servants who have knowledge who stand in true awe of Allah*” (35:28). Many examples of natural phenomena are given in the Qur’an to prompt thought. There are bodies of scholars now in Muslim countries who study the “scientific miracles” in the Qur’an, where they assert it is consistent with modern scientific discoveries, particularly obvious in embryology, astronomy, and geology.

Human beings are also frequently urged to study and learn from history, to travel the earth, see and learn; to think, reflect on themselves, and the world around them. They are told: “*Why do you not use your reason?*” This includes the faculty of conscience, or the “reproaching soul” (*al-nafs al-lawwaama*). Allah inspires the human soul “*with knowledge of what is right and wrong. The one who purifies it succeeds, the one who corrupts it fails*” (91:9–10). The limited time humans have on earth is their chance to do good deeds and make up for bad ones, “*before death comes to one of you and he says, ‘Lord, if you would only relieve me for a while I would give in charity and become one of the righteous’ God does not relieve a soul when its time comes. God is fully aware of what you do*” (63:10–11).

The Qur’an says that Allah created the first human being with His hands from “an essence of mud” (23:12), and breathed into him “from His spirit,” but this brief description is not to be understood literally or necessarily taken to contradict scientific facts, in the same way as Allah cannot be understood as having hands and a mouth to breathe with: “*There is nothing like*” (42:11). Muslim theologians say that when thinking about Allah, He is unlike any image that springs to mind. After the first couple, humans are created in stages in the womb, then through infancy, childhood, adulthood, old age, and death and another stage after death when eventually Allah will resurrect them (23:13–16; 22:5–7).

With this background, the theory of evolution did not seem to disturb Muslim scholars; in fact, long before Darwin, a theory of evolution by natural selection can be found in the works of

the Muslim scholar al-Jahiz (160–256 AH/776–869 AD) who said, in his *Book of Animals*:

Animals engage in a struggle for existence; for resources, to avoid being eaten and to breed. Environmental factors influence organisms to develop new characteristics to ensure survival, thus transforming into new species. Animals that survive to breed can pass on their successful characteristics to offspring.

However, in al-Jahiz’s work, this process remains subject to the will of Allah.

The Qur’an states that Allah created the heavens and the earth “in six days,” but that these are not days according to our reckoning. The Qur’an speaks of a certain day “*whose measure is 50,000 years*” (70:4). Days in this sense seem to mean stages; Allah’s time is different from time on earth. When people are resurrected to face Him, they will feel as though they have stayed on the earth/in the grave for only “*a day or part of a day*” (23:113–114), “*an evening at most, or morning*” (79:46).

In the earthly dimension however, “*Everything has its measure with [Allah]*” (13:8). “*He made the Sun a shining radiance and the moon a light, determining phases for it so that you might know the number of years and how to calculate time*” (10:5). This is true not only of time but of everything else. He has determined a time for each individual and a time when the world comes to an end (6:2) “*There is not a thing whose storehouses are not with us. We send it down only according to a well-defined measure*” (15:21). “*He keeps count of everything*” (72:28).

With all Allah’s exhortations and observations in the Qur’an about the universe and all it contains, it is not the aim of His holy scripture to be a repository of scientific facts. It is enough that it urges believers to think and reflect and find out more for themselves. Indeed it makes this an obligation on them. It says, “*It is Allah who brought you out of your mothers’ wombs knowing nothing, and gave you hearing, sight, and minds*” (16:78). The Qur’an condemns “*those who have hearts they do not use for comprehension, eyes they do not use to see, ears they do not use to hear. They are like cattle – no, even further astray: these are the ones who are entirely heedless*” (7:179). The first verse of the Qur’an

revealed to the Prophet Muhammad puts knowledge on a par with the creation of man. “*He created man, ... he taught man*” (96:1–5). God swears “*by the pen and what they write*” (68:1).

The Qur’an states that Allah honored human beings above many of His creations. He gave human beings the trust (*amaana*) of moral choice, *khilaafa* (stewardship) of the earth, and power over many of His creatures, instructing them, “*Do not corrupt the earth, after it has been set right*” (7:56). Yet “*Corruption has flourished on land and sea as the result of people’s actions and He will make them taste the consequences of some of their own actions so that they may turn back*” (30:41).

All humans are one big family, “*People, We created you all from a single man and a single woman and made into races and tribes so that you could get to know one another. In Allah’s eyes, the most honoured of you are the ones most aware of Him: Allah is all knowing, all aware*” (49:13).

Being aware of Allah includes worshipping Him, taking heed of His guidance, and putting it into practice in the world to establish justice, which is among the objectives of sending the scripture and prophets (57:25). The final Judgment gives purpose to our lives and actions here, without which the creation would be futile (32:115; 67:3). This is a central theme of Allah’s message in the Qur’an and it again uses rational arguments to persuade people of the possibility and reality of the Resurrection (36:77 ff; see also 22:5–7).

Because the Qur’an aims to convince people rationally in order to persuade them to accept its teachings, it urges them to reflect and condemns those who follow blindly what they find their forebears, their masters, or their chiefs doing. Words urging the use of reason, thinking, reflection, and consideration occur 183 times in the Qur’an.

However, there are limits to human perception. For humans there will always be an area of mystery (*ghayb*) – it is only God’s knowledge that comprehends everything (2:255):

He knows what is before them and what is behind them, but they do not comprehend any of His knowledge except what He wills. His throne

extends over the heavens and the earth; it does not weary Him to preserve them both. He is the Most High, the Tremendous.

Introduction

Altruism is a well-established concept in evolutionary biology, psychology, and theology. In biology, it refers to behavior, and any coincident motivations, in which one individual aids

another's survival and reproductive success at a cost to its own, whereas psychological altruism relates specifically to the motivational state in which the welfare of another is of ultimate concern. While biological altruism may be purely behavioral, psychological altruism is possible only by moral agents, those able to form conscious intentions. In Christian theology, altruism is usually understood within the tradition of agape – a self-giving love which has its ecclesial origins in the New Testament.

Within the science-theology discourse, the question is how these disciplines relate to one another and, specifically, the extent to which biological explanations can account for altruism within both nature and human culture, including psychological altruism and religious love. This entry proposes that these three forms of altruism are indeed deeply interrelated, although they are by no means equivalent. One problem for such a consonance has been the view of some biologists, most notably those within *sociobiology* and its related discipline of evolutionary psychology, that whatever appears as altruistic is actually selfish at some more foundational level.

Selfishness and Biological Altruism

In evolution, natural selection generally results in establishing and sustaining the traits (and corresponding genes) that enhance individual reproductive success, since the greater the individual's production of viable offspring, relative to others in the population, the more its particular characteristics and genotype will feature in the next generation. This relative fitness of individuals and their genes provides an explanation of physical and behavioral traits, including aspects of altruism. In *sociobiology*, natural selection is depicted as a competitive process in which individuals selfishly vie for resources and mates in order to outreproduce others in their population, and genes selfishly compete to outreplicate other genes (their *alleles*) in the gene pool. Altruism, like other evolved traits, is therefore construed as serving either selfish reproductive or genic ends, and sometimes both.

While there obviously is competition for food and mates, there is also cooperation in nature, especially among the higher mammals. Moreover, sexual reproduction itself is, for many animals, a demanding and risky task as parent individuals expend themselves in producing, and often providing for, as many progeny as possible. Courtship, nest building, birthing, feeding, and protecting the young are all costly ventures. So, if there is selfishness in pursuing reproductive fitness, there is also much sacrifice. Cooperation is even found at the genic level, since most genes which persist in populations are those that cooperate and coact with other genes (the nonalleles which form the vast majority) to produce functional and reproductive individuals – an outcome which is usually good for sustaining populations. So-called selfish genes are therefore cooperators that produce benefits beyond themselves; hence, the selfish metaphor is again evidently inadequate (Rolston 1999). Arguably, the key sociobiological concepts of individualism, selfishness, and competition are derived not from biological nature so much as from the culturally dominant ideology of Western capitalism.

Kin Altruism: Biology and Psychology

In kin altruism, individuals increase the probability of the survival and reproduction of genetic relatives at a potential cost to their own. As some of these beneficiary kin will also carry the genes for kin altruism, the behavior can be sustained through natural selection. While such actions are altruistic with regard to the individual's own body and reproductive interests, they are interpreted by sociobiologists in terms of genic selfishness – the genes in the individual are simply promoting the survival of copies of themselves in the bodies of kin (Dawkins 1989).

This description in terms of selfishness is inappropriate, however, since the genes that are sustained in populations are good cooperators and, in the case of kin altruism, lead to the aiding of other individuals over the self. In addition, kin altruistic acts often involve supporting

a substantial number of nonreplica genes as most species outbreed, i.e., mate with individuals that are not closely related. There is a recent debate about whether the altruism is thereby graded, as summarized in Hamilton's rule, such that there is a preference for nearer kin (those carrying more replica genes) over more distant kin and also whether there is a preference for the more reproductively fertile (those better able to pass on these replicas) over those less fertile. E. O. Wilson has argued that, at least in hymenopteran species such as bees and ants with which the rule was first established, individuals will sometimes assist colony members in ways beyond these gradations.

While the applicability of Hamilton's rule is somewhat disputed, kin altruism itself remains a widely accepted theory with evidential support from a number of species. An often-given example is the alarm calling among some mammals which warns family members that a predator is in the area but risks attracting the predator's attention to the caller. With regard to humans, kin altruism is said to explain the universality of kinship groups and the pervasive nepotism in societies, systems of favoritism that are supported by cultural norms including religious prescriptions on love.

Clearly, humans do form strong attachments to family members, in particular to those in the immediate family, and sometimes these alliances are nepotistic such that concern for kin excludes the rightful care of others. These bonds may be mediated through unconscious odor and visual cues such that individuals prefer those who look and smell similar to referential figures like parents. The primary means of kinship attachments, however, are probably the close associations forged around the parent-offspring unit. Both familiarity and similarity of situation, such as those naturally occurring in the familial setting, foster empathy; it is easier to understand and identify with the experience of those we know and who are like us in some way.

Empathy owes its evolutionary origins, to some extent, to the parent-offspring relationship. Although this relationship is properly part of individual reproductive fitness, it is sometimes

included in kin altruism, and it forms the core of family bonds. Since parental care is costly, especially in humans where it is intense and prolonged, empathy is critical, as such care could not have been supported solely by the self-regarding instincts involving innate aversion to uncomfortable or painful stimuli and attraction to pleasurable ones. Although these capacities are necessary for survival and even for empathy (we cannot understand another's pain and pleasure without first knowing our own), empathy itself is an other-regarding response which acts counter to self-concern. (The other-regarding character of empathy is seen in the psychological studies by Batson 1991). It enables the parent to vicariously experience the emotions and needs of their offspring and to place these needs beyond their own immediate gratification. This ability to identify with others is augmented by human reasoning and imagination, which also facilitate another important element in other-regard: the appreciation of the other as a subject, one who has a unique emotional and cognitive life and is capable of their own desires, intentions, and goals.

These other-regarding senses enable humans to express a psychological altruism toward their children and other kin which transcends Hamilton's rule. So for reasons very different to that of bees and ants, the human care of kin is not dependent upon the degree of shared replica genes. Humans can also exhibit egoism and hedonism which entail the pursuit of self-interested goals or pleasure, in preference to the care of others, including kin, and even at the expense of their own reproductive interests. Whether such instances of empathetic altruism and of egoism should be categorized as evolutionary mistakes and exaggerations, as some claim, or as capacities with particular moral obligations, is an ideological and not biological issue. Indeed, evolution has generated the human felt need for an ideological framework; it has forced humans to search beyond their biological natures for a metanarrative within which to resolve their mix of self-regarding and other-regarding motivations.

Kin Altruism and Agape Love

In the New Testament, *agape* includes the love of kin, and in its character resembles psychological altruism (The Holy Bible: New Revised Standard Version 1995). It requires a deeply attentive other-regard, which carries the potential for self-sacrifice on those occasions when the other's needs should be placed before one's own. It is contrasted with the self-interest of egoism and hedonism which are themselves explicitly prohibited. Yet *agape* also bears its own distinctive elements for, alongside the prohibitions and the *agape* commands, there is the transforming experience of humility and divine love. With the sense of awe before the greatness of the transcendent Deity, the self is compelled to acknowledge that it is not ultimate (suggested by Post (2002)). More profoundly, humility and love are experienced in the Divine's own immanent *agape* as revealed in the crucified Christ who died on behalf of humans to forgive their failure to love. In identifying with this divine act of grace the individual is thereby freed from self-preoccupation and enabled to respond with alterity and agapistic love toward others.

With regard to kin, the New Testament texts assume the appropriateness of familial bonds, particularly within the immediate family, which is perhaps indicative of an implicit recognition that these kinship ties are innate. Nonetheless, they are not just accommodated as presumed practice; they are also explicitly rooted in the divine will. This is evident in texts such as 1 Timothy 5:8: "But if anyone does not provide for his relatives, and especially for members of his household, *he has denied the faith*." The love for natural family is a basic element in the agapistic commitment of believers.

The constraints that are set upon this familial love, however, ensure that it does not amount to nepotism. The ultimate priority in love is not the natural family but Christ. In the Gospels, Jesus' teaching requires that believers should be willing to leave their families for his sake, a setting of priorities that is found in the practice of the early church. While this love for Christ takes precedence, its consequence is an enhanced regard for

others for, in accord with the divine will, devotion to Christ requires love for kin as well as nonkin. Thus, there is support for familial love but not nepotism, for the love of kin is both deepened and constrained.

Reciprocal Altruism: Biology and Psychology

In evolutionary theory, direct and indirect reciprocity are the two main forms of reciprocal altruism, the cooperation between nonkin individuals. Direct reciprocity entails exchanges of altruistic acts between individuals over a period of time, in which the overall benefits outweigh the costs of the altruism. As gains are invested into each partner's reproductive success, the behavior is perpetuated in the population through natural selection. Reciprocity can be observed in a diverse range of species from the food sharing among vampire bats that roost together to the primate exchanges in food and grooming services. Critics have suggested, however, that immediate individual gains are sufficient to explain nonhuman reciprocity, for example, perhaps the bats only feed hungry roost mates so that they can sleep without being pestered.

In indirect reciprocity, an individual cooperates or may even assist another without expected return, so long as an audience is present that will be induced into future reciprocal exchanges with the altruist. As this assumes an ability to establish a reputation and evaluate relationships – knowing and remembering who offers aid and who fails to repay debts – it is found only among the most social and cognitively able species, primarily in humans. Since reciprocity benefits an individual's reproductive and genic fitness, it is viewed by sociobiologists as selfish. There is also an expectation of widespread cheating (where individuals try to access the gains of reciprocity while minimizing their contribution or giving nothing at all) and of subsequent counter-reprisals. (The general features of reciprocity are given in Dawkins *op. cit.*, pp. 166–188, 202–233, (Trivers (1985) and Nowak & Highfield (2011)).

The existence of direct and indirect reciprocity is supported by human game experiments in which volunteer participants behave in a tit-for-tat manner in exchanges of money. Most players cooperate in equitable exchanges, and those that cheat (defect) by giving an unfair contribution are often punished by the other player's subsequent defection. When the past behavior of participants is made known, reputation becomes important, and players are more generous toward cooperators than defectors. Interestingly, however, some game participants (so-called strong reciprocators) go beyond reciprocity by punishing defectors and rewarding cooperators at overall cost to themselves – an evolutionary explanation for this behavior is still being discussed. Some biologists, including sociobiologists, assume that reciprocal game results reflect general human social behavior with nonrelatives. They interpret Christian moral teachings such as the golden rule, "In everything do to others as you would have them do to you," and the command to "love your neighbor as yourself" as advocating reciprocity, and they see the story of the Good Samaritan in terms of reputation building (discussed in Rolston, *op. cit.*, pp. 248–260, and also Ruse (1994)).

Reciprocity is also used to account for the wide spectrum of emotions and abilities in human psychology. Deception of self and others, for instance, facilitates cheating by allowing, respectively, the feigning and the realistic posturing of sincerity. Guilt is explained as a means of redress when one is found to be cheating, so that reciprocal relationships can resume. Shame indicates an individual's inferiority in reciprocal encounters which will be resolved either by appeasing superiors or by expressions of anger which preempt any exploitation. Contempt allows an individual to defect from reciprocal relationships that are not productive, and gratitude acts as an inducement toward further generosity by the donor. (Reciprocal explanations of human emotions can be seen in Fessler and Haley (2003)).

Although it is entirely reasonable that some human emotions and cultural norms have evolved to effect reciprocal relationships, nevertheless,

the explanatory power of reciprocity is limited. Certainly, the gains of reciprocity are not always invested in human reproduction, and with regard to its putative universality, while humans use reciprocity in exchanges of goods and money, a distinction is commonly made between this economic context and a relational one, such as concern for the welfare of a vulnerable person. The former will be motivated by reciprocal interests, but the latter will entail an other-regard that surpasses reciprocity. Similarly, while reputation building is permitted in an economic context, such as for being a fair tradesman, it is generally unacceptable within personal relations. Even in friendship, one of the most seemingly reciprocal of personal relationships, the ideal is not of returned benefits but a mutual psychological altruism. Indeed, the similarities in circumstance and interests which are common between friends ensure a deep empathetic regard. So it is hardly surprising that direct reciprocity and indirect reciprocity are found to be the primary modes of behavior in game exchanges of money, and while this shows that reciprocation is part of the human makeup, it does not indicate its comprehensiveness.

Moreover, how humans actually engage in both economic and personal relationships is somewhat open. In trade exchanges where the individuals are motivated by a concern for both self and others, the consequence will be fair reciprocity. In contrast, cheating and deception occur where there is an egoistic preoccupation with the self and simultaneous de-emphasizing of the other-regarding senses. These biases may be initially formed consciously, but, like all emotive responses, they may then become ingrained by habit. Even self-deception often has an initial conscious element in the repeated internal justification of the behavior. The specific meaning or content of human emotions also depends upon how the individual resolves their self-regarding and other-regarding propensities. So, for example, the expression of guilt may be entirely self-concerned feelings of unease generated only by what others may think, or it may be a genuine sense of contrition stemming from an empathetic awareness of how others have been wronged.

Thus, fairness and cheating, sincerity and deception, reciprocity, psychological altruism, and egoism are all possible within human nature.

Reciprocal Altruism and Agape Love

The New Testament assumes both the acceptability of reciprocation in economic contexts and its appropriateness in terms of fairness and justice – “the laborer deserves to be paid.” The ideal for personal relationships, however, is an agapistic love which transcends reciprocal interests. Even the appropriate *agape* love for self is ultimately other-regarding, as its final locus is thankfulness and love toward God who both created and forgave the self. Nonreciprocity is particularly evident in the golden rule, where the focus is not on returned benefits but upon treating others in the way that the self would want to be treated *regardless* of their response. Hence, in the Matthean gospel, it is required in “everything,” in all and every circumstance, an inclusivity which is emphasized by its setting within the love for enemies in the Lukan text. This love which transcends enmity, both in terms of nonretaliation and generous care, is also the context for Jesus’ parable of the Good Samaritan. Moreover, in the command to pray for one’s enemies, an empathetic regard is engaged as the believer takes up the enemy’s needs and welfare and acts as an advocate in presenting them before God. Prayer, in particular, makes it possible to transform the self-concern provoked by enmity into *agape* love.

Reciprocity is also very clearly transcended in the priority within *agape* love that is given to the weak – individuals without the means of returning benefits. This includes those who were marginalized and vulnerable in ancient society such as the poor, disabled, widows, and orphans. The care of such persons is not for reputation building, as such deeds are to be done in secrecy and even the self is not to dwell on the goodness of the action. This care for the vulnerable, however, necessarily involves potential conflict with those who oppress the weak, and there are indeed instances of confrontation with such enemies alluded to in the New Testament. This should

not be interpreted as an inconsistency within *agape* love such that the love for the weak supersedes that for the enemy; the purpose is both to protect the weak and to bring the enemy to a proper regard for God and others.

Such expansive *agape* love is often criticized as being motivated by the promise of reciprocated eschatological rewards. Certainly, the texts refer to rewards for those who love Christ more than their natural families, who love their enemies, and who show compassion to the vulnerable and do not reputation-build in the process. But these rewards are nonreciprocal in terms of both motivation and content. The only acceptable motive in *agape* love is the genuine concern for the other, not a focus upon the reward. This finds its most poignant expression in the exposition of love in 1 Corinthians 13 and in the Gospel tradition that the “first will be last, and the last will be first.” Paradoxically, the one who loves others receives rewards, while the one who seeks their own benefit, including rewards, receives little or no recompense. With regard to content, it is God who is the primary reward: the eschatological vision is that of being fully able to love and worship God, as well as participating in a completely united and agapistic human community. The reward is not concerned with reproduction, much less egoism, but with the consummation of agapistic love, its perfect and full expression.

Group Altruism: Biology and Psychology

Group selection theorists have recently proposed that groups can function like individuals, as adaptive superorganisms, that compete to outlast and outreproduce other groups. This relative group fitness may include differentials in birth and mortality rates, susceptibility to group extinction, or differences in their propagation of new groups. Among the traits subject to group selection are the prosocial ones such as altruism; for the groups containing altruistic individuals, those willing to partially forgo their own welfare and reproductive interests in order to aid group members are able to outcompete the groups which exhibit

less internal solidarity. There is a necessary ambivalence in group altruism as care must be expressed only within the group while toward outsiders there will be indifference or open hostility. As Elliott Sober and David Sloan Wilson say, “Group selection favours within-group niceness *and* between-group nastiness” (Sober and Wilson 1998).

While there is still debate about whether group selection occurs in nature, it has become an increasingly popular means of explaining the forging of groups in human society, including religious affiliations. It is argued that religions, like political parties, nations, and tribes, establish group boundaries that identify those who belong and those who do not. They provide instruction and sanction of ingroup altruism and outgroup apathy or hostility. These are particularly binding in theistic communities where they are endorsed by a moral deity, not least because this supernatural and invisible agent is ever watching. Such a vigilant divine presence is deemed particularly important during times of environmental crises when group solidarity is most fragile – a cited example of this is the frequent experience of water scarcity in biblical Israel. Religions such as Christianity are also said to be particularly effective in solving the problem of cheats or free riders – those who want to benefit from the group coalition without bearing the cost of contributing to group welfare. Costly signals such as rituals, prayer, charitable commitments, and especially virtues like self-giving love make extensive demands upon the individual. These deter cheats and also facilitate trust within the group; the signals are symbols of the individual’s genuine commitment to the group’s shared ideals and aims (Norenzayan and Shariff review group and reciprocal explanations of religious altruism – Norenzayan and Shariff (2008)).

Clearly, humans do associate in exclusive groups with resulting rivalries between religious communities, nation states, and even scientific laboratories. Most likely, these ingroup bonds are the result of the empathetic attachments that are formed between those who are familiar with one another or who share the same cultural background, ideological views or shared goals. These

are personal reasons, however, and need not be related to group survival and reproductive outcomes. In fact, just as some ideologies form exclusive group identities which legitimize intergroup conflict (group theory itself could be used in this way), others may choose to extend care beyond the group boundary. One often-given instance is the choice of some charitable individuals and organizations in the West to express empathetic care for, and provide aid to, poorer countries. Every group, therefore, must be evaluated by its own particular ideological commitments.

Group Altruism and Agape Love

The New Testament texts undoubtedly envisage a deeply bonded ingroup community, one in which the familial metaphor of brothers and sisters unites a culturally and ethnically diverse people. Such kinship terms mediate an empathetic altruism, for cobelievers are not alien but belong within the natural intimacy of the immediate family. This community is also demarcated from the rest of society – most pointedly in the Johannine description of them as “not of the world.” There are prescriptives for both communal love and group separateness. Yet the latter is primarily concerned with the internality of believers not being drawn away from their prior commitment to God and toward idolatry. That it is not about external human relations is evident in Jesus’ prayer in the Johannine gospel itself: “I am not asking you to take them out of the world, I have sent them into the world.”

Indeed, there is no expectation of intergroup rivalry as the community was not to displace other groups in society, such as kin and civic units, nor even to restrict the activities of other religious communities. There is, rather, a commitment to love all those outside the group boundary. Even the community’s ingroup love was intended both for the support of its members *and* for outsiders for whom it was a witness to the reality of Christ and the divine love. Those so drawn to Christ were, of course, welcomed into its communal life. This outgroup love cannot be considered a costly signal for, although its sheer

expansiveness may be a potent excluder of free riders, the agapistic commitment to outsiders transcends a group theory explanation.

Conclusion

Agapistic love evidently encompasses psychological altruism and some aspects of biological altruism, but it has its own distinctive character in a radical humility and self-giving which is formed around the nature of God as revealed in Christ. A criticism of such *agape* love is that it is too costly and universal to be bearable by its adherents – it surpasses the inherent limits of human capacity. Indeed, *agape* love is constrained for while there is a commitment to love all others, each individual's love is bound by both circumstance and calling, that is, to those within their normal realm of influence, as well as those who may be outside their immediate context but to whom they are particularly called. Encountered within both categories will be individuals and communities who are outside our kin, reciprocal and even group affiliations.

The more serious criticism is that this love bears no relation to reality, for even those who self-consciously adhere to such agapistic love fail to fulfill it. Certainly, love competes with egoism in human nature, and *agape* itself competes with other ideologies in human society, not least the self-interest espoused by contemporary Western culture. There is no reason to abandon the ideal, as through the New Testament tradition of received forgiveness for past failures, restoration of commitment and empowering by the Spirit of Christ, *agape* can be constantly renewed.

Alzheimer's disease

Rudi D'Hooge and Detlef Balschun
Laboratory of Biological Psychology,
Department of Psychology, Katholieke
Universiteit Leuven, Leuven, Belgium

A neurodegenerative disorder that leads to progressive dementia. First symptoms include impaired memory, but later on also thought and speech processes are affected, and finally patients become completely disabled and die. Its classical neuropathological hallmarks include intracellular neurofibrillary tangles and brain deposition of amyloid protein.

Description

The neurobiology of amnesia is concerned with the way information is stored in the brain, and with what goes wrong when this process fails. In this sense, it largely overlaps with the study of memory (see ► [Memory](#)). It is mostly based on the study of normal and amnesic humans as well as animals, but also benefits from other sources of knowledge. It aims for a better understanding of the human mind, and to provide ways to help people with memory disturbances.

Self-identification

Science

The study of amnesia is a science. It is based on the scientific method and the systematic investigation of hypotheses. Nevertheless, since its object of study is also perceived subjectively, some of its questions are open for speculation based on this kind of experience rather than on objective data.

Characteristics

Research in amnesia is concerned with the very nucleus of identity, which is memory, leading it to offer privileged insights about the mind and the human condition. It is also an area of neurobiology which draws knowledge from a very wide range of subfields, ranging from cognitive psychology to molecular biology.

Relevance to Science and Religion

The neurobiology of amnesia, although not specifically concerned with religion, has implications for concepts such as *self* and *human nature*, as it provides clues on how personality and self-awareness persist when memory is disturbed. Also, the fact that memories can incorporate subjective meanings and even imagined experiences during their processing leads to

questions about the veracity of empirical knowledge. Such issues have implications for the Science and Religion debate.

Sources of Authority

Although memory has been a subject of philosophy for centuries, its experimental study largely started in the late nineteenth and early twentieth centuries with precursors such as Hermann Ebbinghaus, who started the study of association formation in humans, and Ivan Pavlov, who developed the first conditioning paradigms in animals.

The study of amnesia in human subjects gained impulse with the 1957 description of patient H.M., who underwent removal of the temporal lobes for the treatment of seizures and could not form new declarative memories after the surgery. This and other cases led to the distinction between anterograde (the failure or inability to form new memories in the long term) and retrograde amnesia (a dysfunction in the ability to retrieve established memories), leading to a distinction between memory acquisition, consolidation, and retrieval mechanisms. It also helped support the hypothesis that memories undergo late forms of processing which continue to occur over large periods of time (i.e., years) after their initial acquisition, such as systems consolidation.

Ethical Principles

Research in amnesia is usually guided by national legislation on research on human and animal subjects, as well as international research guidelines such, as the Declaration of Helsinki.

Key Values

The study of the neurobiology of memory and amnesia is driven by the principles of (a) alleviating the suffering of patients with memory dysfunctions (see ► [Dementia](#)) and (b) providing

knowledge about the mind to increase understanding of the human condition.

Conceptualization

Nature/World

Amnesia researchers tend to view nature in the usual way of the natural sciences (i.e., within the limits of what can be empirically observed); however, its findings are not particularly pertinent to such concepts.

Human Being

A human being is seen as arising from the interaction of a *genetic* background with the *environmental* events occurring during an individual's lifetime. These events affect the brain through synaptic plasticity to make up an individual's neurobiological structure. Synaptic plasticity is the phenomena through which synapses between neurons can change their efficacy, thereby encoding information which is thought to underlie memory.

Life and Death

Amnesia research sees brain function and consciousness as one of the key factors defining "life" in humans. As for the larger concept of "life" in nature, it is not particularly pertinent to such a topic.

Reality

Amnesia research tends to view objective reality in the same framework as the natural sciences. However, as other areas of neurobiology, it acknowledges that "empirical" reality is ultimately a subjective perception.

Knowledge

Amnesia researchers usually think of knowledge in a personal level as the abilities and information which can be retrieved from memory and used. However, they understand that knowledge can also be discussed in a collective scale.

Truth

Amnesia researchers usually believe that there is "truth" in understanding the functioning of

the physical world. However, truth is considered an abstract concept which we approach partially through scientific models, with no assumptions on the existence of an absolute truth.

Perception

Perception is the information which an individual acquires through the senses. It is thus a necessary first step for memory formation.

Time

Amnesia research views time in the general framework of physics and the natural sciences. However, it also acknowledges the existence of a subjective sense of time, which is part of the information contained in memories.

Consciousness

Consciousness is a very controversial concept in neuroscience, even within specific subdisciplines. Most definitions describe it as an organism's representation of itself and of its world, or as the feeling of awareness derived from perceptions and thoughts. Memory researchers acknowledge the existence of declarative memories, which can be consciously retrieved by a subject, but also of nondeclarative memories, such as abilities and reflexes, which can influence behavior through unconscious mechanisms.

Rationality/Reason

In amnesia research, reason is generally seen as the foundation of science. In neurobiological terms, it can also be an object of research, when viewed as the way in which an individual uses knowledge to solve problems and make decisions.

Mystery

As a natural science, amnesia research usually sees mystery as something about which we lack comprehension, not as an intrinsically incomprehensible entity. Some neuroscientists also study concepts such as "mystery" and "faith" as subjective perceptions arising from the brain.

Relevant Themes

As memory is a subject so vital for human experience, it has been constantly revisited by other sciences and arts, such as philosophy and literature. Amnesia is also a popular topic in literature and cinema, possibly because it allows one to discuss the limits of the human self in these conditions. However, the depiction of amnesia in such works is usually inaccurate, following poetic license rather than science.

Specific definitions of memory are also central for many religions. Spiritual beliefs in past lives, for example, has led some to hypothesize that memories might be transferred to future generations or unrelated individuals. However, this is also contrary to what neurobiology observes and predicts based on empirical evidence.

[Nestinari](#)

Description

The term “Anastenaria” (from the Greek verb *anastenazo*, to sigh) is a plural noun which refers both to a tradition and the members of that tradition (singular: *Anastenari*). The Anastenaria are religious communities of Northern Greece and Southeast Bulgaria (where they are called *Nestinari*), known for their devotion to saints Constantine and Helen and the fire-walking rituals they perform in their honor.

This tradition was maintained in various villages of Eastern Thrace during the time of the Ottoman Empire by Greek-speaking populations. The most notable of those villages was Kosti, in the area of Strandja. After the Balkan Wars, during the first quarter of the twentieth century, when Bulgaria gained control of this territory, those populations were forced to migrate to Greece. Today, most of their descendents live scattered around Greek Macedonia and they perform their rituals in five villages: Ayia Eleni, Langhadas, Meliki, Mavrolefki, and Kerkini. A handful of Bulgarians still perform these *rituals* in their original location near the Black Sea coast of Bulgaria.

The origins of this tradition are unknown. Certain Greek scholars have argued that it is related to the ancient orgiastic Dionysian cults. However, this theory was ideologically motivated and lacks any evidentiary support whatsoever. It was constructed as part of a general effort on behalf of Greek nationalist folklorists to prove

the continuity of Greek civilization, from ancient to modern Greece. Nevertheless, it became the dominant view of the Anastenaria for more than a century, and caused a persecution of this tradition by the Greek Church, which is to this day very hostile toward it (Danforth 1989; Xygalatas 2011).

The Anastenaria are devout and practicing Orthodox Christians; however, in addition to church religious life, they observe an elaborate annual *ritual* cycle with several ceremonial events around the year, all of which are based on important days of the Orthodox calendar and are related to various saints. Special emphasis is given to saint Constantine, who is considered to be the founder of this tradition, and his mother, Saint Helen. According to one folk legend, at some indefinite time in the past, the church of saints Constantine and Helen in Kosti caught fire. As the church burned, the villagers heard the icons crying for help. The bravest rushed into the burning church to save them and neither they nor the icons were harmed by the fire. To commemorate this miracle, the people of Kosti organized an annual *fire-walking ritual*.

Each community of Anastenaria has its own sacred spaces, exclusively used for religious purposes: *Fire-walking* is performed within a fenced circular field of about 30 m in diameter. Most ceremonial activities take place in a rectangular building called the *conaki*. There is also a chapel (*parekklisi*) and a sacred well (*ayiasma*), from which holy water is drawn. The most important sacred objects of the Anastenaria are the icons of the saints, which are passed from one generation to the next. These icons are thought to carry some of the power of the saint they depict and to have miraculous properties.

The biggest events in the religious life of the Anastenaria are two festivals, that of Saint Athanasius in January and especially that of Saints Constantine and Helen in May. These festivals incorporate elaborate sequences of *ritual* actions, including processions of the icons around the village, purifications with incense and water, communal meals, and an animal

Anastenaria, Fig. 1 The Anastenaria dancing barefooted over the fire

sacrifice. Each festival lasts 3 days, and during that period, the Anastenaria dance ecstatically for many hours to the sounds of lyres and drums. The festival culminates with a *fire-walking ritual*, where the participants, carrying the icons of Saints Constantine and Helen, leave the conaki and continue their dance barefoot over glowing-red coals without getting burned (Xygalatas 2012) (Fig. 1).

Self-identification

Science

The Anastenaria do not in any case self-identify as a science. However, they often claim the ability to explain and influence the natural world with the use of their icons and the performance of their *rituals*. According to these claims, they can often predict the future, heal the sick, bring rain and fertility, etc.

Religion

The Anastenaria are a religious group. However, they do not self-identify as a separate religion. They are devout Orthodox Christians, who fully endorse the doctrines of the Greek Orthodox Church, participate in its *rituals*, and honor all its saints, but have a special place in their worship for saints Constantine and Helen. They also have a distinct *ritual* cycle, which

includes *rituals* that the Greek Church opposes and considers as pagan.

Characteristics

The Anastenaria are a distinct tradition in that they combine Orthodox Christian doctrine and liturgical life with *ritual* actions that are not part of Orthodoxy, such as animal sacrifice, ecstatic dance, and *fire-walking*. Furthermore, although the Anastenaria recognize the Trinity and all the saints of the Orthodox Church, their worship is mostly focused on two saints, Constantine and Helen, and particularly the former, to the extent that some observers have described it as a cult of Saint Constantine.

Relevance to Science and Religion

The Anastenaria themselves are not explicitly interested in the disciplinary relationship between science and religion, as they do not see a conflict between the two domains. However, scholars who study this tradition often debate about the priority of scientific or religious explanations of incombustibility. Scientists have asserted that fire-walkers do not get burned because of the poor conductivity of coal and short time of contact. They point out that those who perform fire-walking around the

world, whether religious or not, do not usually get burned. On the other hand, participants as well as various scholars argue that science cannot explain *fire-walking*. According to this view, *fire-walking* is a mystery, only explainable in terms of divine intervention, and nonbelievers who perform it will get burned unless they somehow manage to cheat.

Sources of Authority

The Anastenaria have no prophets nor sacred texts or any other form of written tradition, although as Christians, they accept the authority of the Bible and Jesus Christ (Danforth 1989, Xygalatas 2011). The official leader of the group is the *archianastenaris*, who initiates their *rituals*; however, he is rather considered as “the first among equals.” Important decisions regarding the tradition are often made by popular consensus, while the succession of an *archianastenaris* is decided by a form of council of elders, called “the twelve” (although the number is merely symbolic and in practice varies). In general, elders are seen as much more knowledgeable and therefore authoritative than youths on matters of tradition.

Ethical Principles

For the Anastenaria, the world is governed by the will of God and the saints, particularly Saint Constantine, who is the progenitor of the Anastenaria and has an active interest in their affairs, guiding and protecting them, helping the pious, and punishing the sinful. The icons of the saints contain part of their essence and have the power to heal the sick.

Key Values

The Anastenaria must serve the saints and look after their icons, lead an ethical life, and be good Christians. If one receives the saints’ calling in the form of a dream or other “*sign*,” one must become a fire-walker; failure to obey will cause the saints’ punishment in the form of misfortune.

Becoming an Anastenari is a life-long commitment, as withdrawing can evoke the saints’ wrath.

Conceptualization

Nature/World

As Christians, the Anastenaria see nature as God’s creation *ex nihilo*. As such, nature is not sacred in itself and it is not to be worshiped but admired and revered as God’s creation. Thus, those elements of the physical world that are considered as holy for the Anastenaria, such as their sacred wells (*ayiasmata*), are seen as such not because of some intrinsic property, but only to the extent that they provide some material means for the manifestation of divine properties.

Human Being

The Anastenaria accept the Christian view of human beings as created by God and consisting of a mortal body and an immortal soul/spirit.

Life and Death

As Orthodox Christians, the Anastenaria believe that life was created by God. Whether present life forms were created by a miraculous creative act (creationism) or through evolutionary processes (theistic evolution) is a wider debate in Christian theology, not directly relevant to the Anastenaria.

According to Orthodox doctrine, death brings the dissolution of the body, while the soul awaits the Final Judgment, which will take place at the Second Coming of Christ.

Reality

As Orthodox Christians, the Anastenaria believe that there is a physical reality that is knowable and finite as well as a divine world that is beyond the reach of human experience, unknowable, and timeless. However, God’s will is *manifested* in the physical world through His workings and those of the saints, who function as mediators between Him and human beings. Most important among them is Saint Constantine, who often performs miracles, appears in people’s dreams and visions, and sends them meaningful signs.

Knowledge

Religious knowledge within the tradition of the Anastenaria is orally transmitted and comes from two main sources. The first is personal experience and its individual or collective interpretation. Dreams and visions are seen as *manifestations* of the saints, while unusual events are often considered as divine *signs* or miracles performed by them. The second source of religious knowledge comes from oral narratives that get transmitted from one generation to the next by word of mouth. Those usually involve the myths and legends of the Anastenaria that talk about the origins of *fire-walking*, the lost homelands, and an idealized past, when the saints interacted directly with their forefathers, who were wise and pious. This transmission is not regular or explicit but rather occasional and even rare. Elders are generally considered as much more knowledgeable and wise, even if this knowledge is never displayed or challenged.

Truth

Truth can be the understanding of the physical or the metaphysical world. The former can be grasped by humans only in part, while the latter is unattainable by them. However, in certain occasions, the saints may reveal fragments of divine truth through their *signs* and other *manifestations*.

Perception

Human perception is limited to the physical world, while metaphysical things are beyond our perception. However, certain devout persons can often perceive things that are outside normal sensorial awareness, through the mediation of the saints, who send them their *signs* in dreams, visions, as well as in everyday life.

Time

As all Orthodox Christians, the Anastenaria have a linear concept of time, which has a beginning and an end. The beginning is the act of creation by God and the end will come with the Second Coming of Christ and the Final Judgment, which will bring the consummation of the world and time.

Consciousness

In addition to normal consciousness, certain people among the Anastenaria are thought to have a special kind of consciousness, which allows them to communicate with the saints, most commonly Saint Constantine. In particular, many Anastenaria claim that they enter this altered state of consciousness during the performance of *ritual* dance and *fire-walking*.

Rationality/Reason

As people of the modern Western world, the Anastenaria usually rely on reason and science for explanations of the world. However, rationality is not the only source of knowledge. There are things that are inaccessible to human reason, and for those things faith is a better guide. Religious explanations are not usually seen as incompatible with scientific ones. Especially when science fails to provide solutions to everyday problems (for example, when doctors fail to provide healing), religious explanations are sought alongside.

Mystery

The term “mystery” refers to that which is beyond human reason and understanding and can be made known only by divine revelation. The Anastenaria consider *fire-walking* as one such mystery. According to them, the fact that their feet remain unharmed by the fire cannot be explained except as a miracle. Only those who enjoy the protection of Saint Constantine can fire-walk successfully.

Relevant Themes

Fire-walking rituals are performed the world over, but there is no established connection between the Anastenaria and other traditions, with the exception of the Nestinari of Bulgaria, as the two originate from the same tradition.

Anatomy of the Brain

Arthur W. Toga
Laboratory of Neuro Imaging, Department of
Neurology, UCLA School of Medicine,
Los Angeles, CA, USA

Related Terms

[Brain anatomy](#)

Description

Brain anatomy is studied in a variety of ways from cyto- and chemoarchitectural studies to whole brain in vivo maps created using magnetic resonance imaging (MRI). Newer methods such

as diffusion imaging have revolutionized how circuits and structures are mapped in the human brain. The in vivo approaches have greatly improved our understanding of the normal trajectory of brain anatomy during maturational and development changes as well as normal aging. These in vivo anatomical techniques have also transformed clinical neuroscience in the diagnosis, care, and treatment of many neurological and psychiatric disorders. Brain anatomy varies somewhat and studies of populations have revealed variation by anatomic region, gender, handedness, and other demographic categories. Brain tissue can be examined postmortem using a variety of histological, immunohistochemical, and other approaches to identify and characterize its cellular and chemical composition.

The brain is a complex concentration of nerve cells in the central nervous system weighing approximately 3 lb and responsible for sensory perception of the environment, determining and effecting appropriate motor responses, as well as thinking and learning. The brain governs the functioning of all the body's other organs. It is also responsible for instinctual behaviors and integrates current information with past experiences. The brain makes us conscious, emotional, and intelligent.

In humans, the brain is made up of about 100 billion nerve cells, called neurons; supporting cells (glia); and vascular and other tissues. There are numerous neuron types differentiated by structure and function. Encased in the bony cranium, the brain's outward appearance is dominated by two large, almost symmetrical cerebral hemispheres located on either side of a central core known as the brain stem. The brain stem gradually becomes the spinal cord exiting the cranium through an opening at the base of the skull called the foramen magnum.

Self-Identification

Science

Anatomy is, by its very nature, descriptive science. Observing and documenting the structure of the human brain has fascinated students of

biology and medicine for centuries. It is a science that uses exquisitely sensitive instruments capable of dissecting the components of individual cells along with imaging machines capable of witnessing, in a living healthy human being, the neuronal and hemodynamic consequences of thinking and behaving. Both structural and functional anatomy can be defined as a harmonious partnership between a number of scientific disciplines including neuroscience, computer science, physics, and mathematics.

Since anatomy is a descriptive activity, morphological statistics such as shape, size, position, orientation along with reports of the overall cell type, packing density, and other features are used to label and quantitatively measure regions of the brain. Augmenting these descriptions are the neuronal fiber pathways that connect different regions of the brain. These too are compiled into atlases that document the accumulated understanding of brain anatomy. These days, mostly all this activity is done across populations and to compare one subpopulation with another. But more importantly, it is done digitally and computationally, enabling comprehensive statistics and visualizations to be computed and rendered quickly.

The science of anatomy is now often performed, in part, automatically using machine vision techniques whereby algorithmic feature extraction, identification, measurement, and modeling can be performed with little or no human assistance. This science is applied in basic and translational research to normal and diseased brain.

Historically, this field has always considered itself a science as it describes, following observation, features that can be seen and measured of an organ system found in all mammals. Its utility in medicine has only been realized relatively recently. The study of neurology includes comprehensive knowledge of brain anatomy coupled with an understanding of its component functions, diseases, and abnormalities.

Characteristics

Brain anatomy is often the foundation upon which other clinical neuroscientific disciplines

depend. The structure of the brain defines the machinery upon which our understanding of its functions and systems operate. As such, it is fundamental and often linked to many other disciplines related to the nervous system.

Brain anatomy is distinctive as it provides the nomenclature for communicating the location and relationship of structures relevant to the study of neurology and psychiatry and other specialties of medicine. Brain anatomy also classifies structures into systems establishing the relationship between parts of the brain and its functions. As such, it is critical in understanding the consequent deficits following insult from trauma, disease, or other causes.

The modern science of brain anatomy includes coordinate systems that have application in the care and treatment of patients by neurologists, neurosurgeons, and radiologists. Population studies are enabled by the utility of these coordinate systems and the sophisticated mathematical tools for averaging and comparing across subjects that accompany them.

In basic neuroscience, brain anatomy figures prominently in cognitive neuroscience, psychology, and other related fields. Relating behaviors to specific circuits and systems of the brain is a form of functional anatomy studied using MRI, positron emission tomography (PET), transcranial magnetic stimulation (TMS), electroencephalography (EEG), magnetoencephalography (MEG), and other methods. Hence, it is a science that is tightly interwoven with many other specialties of neuroscience.

Relevance to Science and Religion

The science of brain anatomy includes the study of its changes (both structural and functional) over time. The adaptive consequences present themselves in many brain areas across the life span influenced by many factors including experience. As such, a variety of experiential influences have been investigated including meditation and practices of certain eastern religions to determine if and to what extent brain changes can be measured. Functional anatomy

studies in the form of fMRI have been used to measure brain responses to moral and ethical dilemmas. Thus, the science of structural and functional brain anatomy may have relevance to the scholarly area called science and religion. Certainly the emergence of ever more sensitive methods will encourage this line of investigation to continue.

Sources of Authority

Illustrations of the brain underwent a dramatic leap in quality, along with general scientific inquiry, in the fifteenth century (Clarke, et al., 1996; Finger, 2000). Objective survey of brain anatomy along with considerable artistic skill produced increasingly accurate representations of the many of the structures of the brain. Examples include drawings made by Leonardo da Vinci (1498–1504) and Andreas Vesalius (1543). Created during the Renaissance and Age of Enlightenment, these are among the first illustrations of brain anatomy rendered following careful examination of cadaverous specimens. Andreas Vesalius is recognized as one of the greatest of the Renaissance anatomists, one only has to look at his illustrations in his book *De humani corporis fabrica*, 1543, to appreciate the quality of his scientific observation. In 1664, Thomas Willis published his book on the anatomy of the brain and nerves, *Cerebri Anatome*. *Cerebri Anatome* can be considered the first attempt at describing the functional anatomy of the brain. Willis proposed three areas in the brain: the corpus striatum, corpus callosum, and cerebral cortex responsible for the *sensus communis*, imagination, and memory, respectively. Perhaps one of the more important milestones was the functional anatomy mapping of Korbinian Brodmann in the early 1900s. His numerical catalog of cortical areas is still a valuable reference system utilized today.

In modern times, the study of brain anatomy transitioned from gross brain anatomy to cyto- and chemoarchitecture, mapped into coordinate systems and related to other modalities describing brain structure and function. Jean Talairach

(1911–2007) developed a system for stereotactic localization of human brain structures, creating human brain atlases that enabled quantitative comparison of brain anatomy across subjects. With the advent of imaging devices, the power of population studies and replication of findings by independent laboratories and studies defines the authority of this discipline.

Ethical Principles

There are general principles regarding the use of human subjects that are enforced by independent regulatory bodies. These review boards examine the ethics, methods, and usage of all data collected from human subjects to determine the value and risk of each study.

Key Values

Understanding the human brain is one of the greatest quests in science. This is the organ that makes us who we are and hence the value of this discipline is immeasurable. As this discipline is also fundamental to clinical specialties such as neurology, neurosurgery, psychiatry, and psychology, its value can be found in the care and treatment of patients suffering from diseases of the nervous system.

Conceptualization

Nature/World

Nature is conceptualized as the *biological* and *biochemical* foundation of life. The world is where we are.

Human Being

Humans are one of a vast and diverse collection of living things on Earth. Humans are arguably the most advanced intellectually and hence dominate the food chain. We have created a sophisticated culture and environment for ourselves and extended our already highly developed capacity for communicating and thinking.

Life and Death

Life is the coordinated functioning of interconnected organ systems. There are many life forms, each with its own operational requirements. These range from single cell organisms to humans. Death is the extinction of this coordinated functioning.

Reality

Reality, for each of us, is what we can observe.

Knowledge

Knowledge is derived from information and enables understanding. We can communicate that knowledge now with countless media from verbal language to streams of digital bits.

Truth

Truth is perceived fact, indisputable, and absolute.

Perception

Perception is the processed from of signals detected by any of our five senses. Neurological and psychiatric disorders can alter, disrupt or impair perception.

Time

Time can be perceived from internal stimuli such as the last time one had a meal or slept and it can be perceived from external stimuli such as the apparent movement of the sun across the sky. Although we may use devices to quantify the passage of time linked to celestial movements, we also have genes in cells that cycle with time.

Consciousness

Consciousness is responsiveness to any external physical stimulus. There are different degrees of consciousness, some of which are modulated by internal conditions such as wakefulness and attentiveness.

Rationality/Reason

Rationality is appropriate behavior for the situation. In part determined by culture, rational behavior is considered appropriate and acceptable. Some diseases of the brain can render an individual incapable of rational behavior.

Mystery

Mystery is that which is presently unknown. The goal of science is to unlock that which at first appears mysterious.

Relevant Themes

The great challenge that is the human brain begs the question, is the human brain capable of understanding the human brain? This, most complex organ has such remarkable structure and function that many neuroscientists and other students of brain anatomy often marvel at how much we still do not understand. But the wonder of the human brain inspires every scientist who has taken up the journey of discovery.

Anattā

Bhikkhu Anālayo

Center for Buddhist Studies, University of
Hamburg, Hamburg, Germany

Related Terms

Anātman (Sanskrit); Not-self

Description

The teaching on the absence of a self is one of the most prominent characteristics of Buddhism, when compared to other religions. This distinctive feature of Buddhist thought has considerable relevance for placing Buddhism within the dialogue between science and religions, as Buddhist texts take the absence of a permanent self to be the evident outcome of a thorough investigation of all aspects of subjective experience. Such investigation is held to lead to the unavoidable conclusion that a permanent self cannot be found at all. Hence, the notion that such a self exists should be understood as mistaken.

Buddhist analysis distinguishes between twenty possible modes of construing a notion of a self (e.g., Trenckner and Chalmers 1888–1896, I 300), referred to with the term *satkāyadr̥ṣṭi* (Sanskrit) or *sakkāyadiṭṭhi* (Pāli). This analysis is based on the so-called five aggregates, which according to Buddhist thought are the chief constituents of an individual. These five comprise the aggregates of the body, feeling, perception, volitional reactions, and consciousness. Buddhist thought holds that a self cannot be found in relation to these five aggregates in any way, neither by identifying any of the five aggregates as the self, nor by postulating a self as the owner of an aggregate, nor by assuming that the aggregates exist in some way within a self, nor by locating a self within an aggregate.

The type of investigation that leads up to insight into the absence of a self is depicted in

a discourse that according to the traditional account was the teaching given by the Buddha to lead his first disciples to full awakening (Feer 1884–1898, III 66). As a first step in this examination, the discourse clarifies that none of these five aggregates are fully amenable to control, that is, neither one's bodily condition nor what one feels, what one perceives through the sense doors, how one reacts, and what one is aware of by way of consciousness will always be as one would like it to be. Hence, the notion of a self in the sense of an independent controller who wields complete mastery over experience is not empirically verifiable and thus should be considered as not existing in truth and fact.

A complementary line of investigation forms the next step in this examination. This complementary approach begins by inquiring if the five aggregates can be reckoned as permanent. Inspection shows that each of these five sooner or later is bound to change. Hence, the conclusion to be drawn is that each of the five aggregates is impermanent (► [Impermanence \(Buddhist\)](#)). Next follows the query if what is impermanent should be reckoned as unsatisfactory or as agreeable. Although what is impermanent might be agreeable for some time, due to its inevitable change, it sooner or later turns out to be unsatisfactory (► [Dukkha](#)), in that it fails to yield lasting satisfaction. This conclusion then leads to the third and final step in this investigation, according to which what is impermanent and unable to yield lasting satisfaction fails to fulfill the requirements for being regarded as a self.

The argument employed in this investigation serves to clarify what kind of a self the Buddhist teaching of *anattā* rejects, namely, a self that is permanent and endowed with complete mastery over its own field of experience. While the teaching of *anattā* clearly opposes the notion that an eternal core can be found behind the changing processes of the five aggregates that make up an individual, it does not deny the existence of this changing process as such nor the empirically verifiable fact of personal continuity.

An illustrative simile provided in one discourse compares the five aggregates to a chariot (Feer 1884–1898, I 135). The term

“chariot” is simply a convention used to designate a functional assemblage of different parts, like the wheels and the axles. Once taken apart, besides these constituent parts, no chariot as such can be found. Yet, the denial of the existence of an eternal chariot independent of its parts does not mean that it is impossible to drive with the impermanent and conditioned assemblage of parts to which the term chariot refers.

Similarly, although according to Buddhism what makes up the individual person are merely the five aggregates and besides these no eternal self can be found, to assume that the denial of a self leaves no agency for karmic responsibility is considered a mistaken conclusion (Trenckner and Chalmers 1888–1896, III 19). The five aggregates as a conditioned process continue and thus provide the required medium for the taking of decisions and the performance of actions, as well as for their subsequent karmic retribution (► [Karma \(Buddhist\)](#)). As the simile of the chariot shows, to combine the denial of an eternal self with personal continuity does not require invoking two different levels of truths, as is sometimes done in later Buddhist tradition, but merely involves a clear recognition of what is being denied with the doctrine of not-self and what is not being denied.

That the existence of an individual as a changing process is not being denied can be seen from various passages in the Buddhist discourses. These indicate, for example, that bad actions done by oneself will in due course affect oneself (von Hinüber and Norman 1994, Stanza 161) or else that it is by one’s own acts that one defiles or purifies oneself (von Hinüber and Norman 1994, Stanza 165). Even instructions on the practice of mindfulness as a key aspect of the path to awakening explicitly employ terms like “I am walking” or “I feel pleasure” (Trenckner and Chalmers 1888–1896, I 56). Elsewhere, the Buddha is on record for remembering his past lives in terms of “I was reborn” (Trenckner and Chalmers 1888–1896, I 22). In short, even a fully liberated one may still use terms such as “I” or “mine” (Feer 1884–1898, I 14), even though any notion of a permanent self has been forever eliminated.

In the early Buddhist texts, the teaching on the absence of a self appears to have been

predominantly directed toward the insight that no self can be found within an individual. With later traditions, apparently in opposition to what was perceived by some Buddhist thinkers as a tendency by others Buddhist thinkers toward a reification of elements (dhammas) as the basic constituents of reality, teachings regarding the absence of any permanent essence were explicitly applied to these elements. Expositions of the absence of an eternal self also increasingly tend to use the term “emptiness” instead of “not-self.” The notion of emptiness occurs, however, already in the early texts, such as in the dictum that “this world is empty of a self and what belongs to a self” (Feer 1884–1898, IV 54). Thus, the idea that emptiness is all pervasive – in the sense that a permanent essence or self cannot be found anywhere at all – can be traced to early Buddhist thought. As a stanza poetically sums up, by rooting up the view of self and by looking on the world as empty, one would be able to transcend even death (Andersen and Smith 1913, Stanza 1119).

Anatta: Non-self

Ven. Agganyani
German Vinaya Sangha Association (DBO) and
Centre for Buddhist Studies (CBS), Myanmar,
Bruckmuehl, Germany

The doctrine of *anatta* (Pāli) or *anātman* (Sanskrit) is the central, most profound, and typical teaching of Buddhism and Abhidhamma.

Atta stands for “soul” or a permanent self, I, ego, or intrinsic core. *An-atta* is the negation of such a soul or self. The Buddha’s *anatta* doctrine teaches that neither within the five aggregates (*khandha*) – which constitute a being and are bodily and mental phenomena – nor outside of them, can be found in anything that could be regarded as a permanent, self-existing ego-entity, or soul in the ultimate sense.

Anatta, non-self, non-I, non-ego, soullessness, impersonality is the third of the universal characteristics of existence and all phenomena, not only of conditioned phenomena (*saṅkhāra*), but even of the unconditioned *Nibbāna*. *Anatta* can be understood through penetrating the Buddhist doctrine of “Dependent Origination” (*paṭṭiccasamuppāda*), and in more detail and clarity through “Conditional Relations” (*paṭṭhāna*), the seventh book of the Abhidhamma, which teaches the relations and connections of all mental and physical phenomena, which form a huge, complex net of causes, conditions, and effects. Everything one experiences happens because of conditions, and oneself, the subject including one’s observing mind, is conditioned too. There is no inner core, self or soul, that is not subject to

this unstable conditionality, which would be permanent, reliable, to cling to, and identify with. There are only void processes following their own natural laws according to conditions.

Anatta presents itself as uncontrollability. All things, phenomena, and experiences are conditioned and we do not have the power to control these conditions. Therefore, the effect of these conditions, our experience or whatever phenomenon, is not under our control. For example, we cannot make happiness or love stay forever, or sadness, pain, and decay disappear.

The contemplation of non-self (*anattānupassanā*) is one of the three main methods in insight meditation. It discards the clinging to a self. *Nibbāna* appears through the void aspect and the practice leads to emptiness emancipation (*suññatā-vimokkha*) with wisdom (*paññā*) as gateway to liberation.

Anesthesiology

Viji Kurup and Paul G. Barash
Department of Anesthesiology, Yale University
School of Medicine, New Haven, USA

Related Terms

[Sedation](#)

Description

Anesthesia refers to a state where most sensation (primarily pain) is reversibly blocked to facilitate surgical procedures. The discovery of anesthesia was the most significant contribution to the advancement of health care in the world. The origin of the term is credited to Oliver Wendell Holmes, who introduced the word to describe the effect produced by inhalation of ether. The development of the specialty of Anesthesiology as a science began in 1846 after the first public demonstration of the effects of ether in treating

surgical pain by W.T.G. Morton (Smith and Bacon 2006). In the USA, Anesthesiology evolved as a specialty in its own right in the late nineteenth century and Europe followed suit. Today, the specialty of anesthesia encompasses taking care of the patient before, during, and after surgery. Anesthesiologists are experts in airway management, treating pain outside the operating room, and in managing intensive care units and researchers exploring the mechanisms of pain and methods to improve the outcomes of patients after surgery.

Self-identification

Anesthesiology is a scientifically based specialty in the field of medicine. It aims to achieve a deeper understanding of the mechanisms of awareness, consciousness, pain, and the human body's response to surgical stress. Anesthesiologists apply scientific methods of the natural sciences for clinical and basic research as well as for developing diagnostic algorithms and implementing therapeutic regimens. Two well-known methods of surgical anesthesia are General Anesthesia (GA), where the patient is rendered unconscious without arousal to painful stimuli for the surgery, and Regional Anesthesia (RA), where certain regions of the body are selectively rendered insensible to pain. The agents used include inhalational anesthetics, intravenous anesthetics, as well as adjuvant medications, which together can cause amnesia, analgesia, loss of consciousness, and muscle relaxation if needed. Anesthesiology has now branched into the subspecialties of Cardiac Anesthesia, Pediatric Anesthesia, Pain Medicine, Critical Care Medicine, Obstetric Anesthesia, and Neuroanesthesia.

The first American Organization of physician anesthetists was formed in 1905 and called the Long Island Society of Anesthetists. The apex body for anesthesiologists in the USA today is called the American Society of Anesthesiologists (ASA), which got its present name in 1945 (www.asahq.org). Its counterpart in the UK is called the Royal College of Anesthetists, which

was awarded its royal charter in 1992 (<http://www.rcoa.ac.uk/>).

The increase in knowledge in the different subdisciplines has resulted in the evolution of different societies, such as the Society for Education in Anesthesia (SEA), Society for Ambulatory Anesthesia (SAMBA), Society of Pediatric Anesthesia (SPA), and Society for Cardiac Anesthesia (SCA).

Characteristics

Anesthesiology is distinctive among the other specialties of Medicine. The specialty is focused on studying the mechanisms and effect of medications on consciousness, awareness, the changes that take place in the human body during surgery, and its response to surgical stress. Anesthesiologists undertake the complex task of managing the delivery of medications causing GA or RA, as well as monitoring and preserving the vital functions of the patients undergoing surgery while doing this in the safest possible way for the patient.

Relevance to Science and Religion

Anesthesiology has a rich tradition of scientific research both in the laboratory (basic sciences) and in the clinical arena (clinical sciences). It is based on knowledge derived from hypothesis-driven studies and promotes practice of evidence-based medicine.

Sources of Authority

The early authorities in the specialty of Anesthesiology were dedicated physicians who set standards in education and achieved proficiency in the administration of anesthetic agents (Sykes and Bunker 2007). John Snow (1813–1858), a respected British physician, was one of the first to study and calculate dosages for administration of ether and chloroform for surgical anesthesia and described the clinical stages of depth

of anesthesia. He set the scientific basis for the study of the art and science of anesthesia. He published two remarkable books, “On the Inhalation of the Vapour of Ether” (1847) and “On Chloroform and Other Anesthetics” (1858). He administered chloroform to Queen Victoria for the birth of two of her children and bestowed respectability to the science of anesthesia. His work on inhalers set the stage for the evolution of equipment for delivery of anesthetic agents in the latter half of the nineteenth century.

Arthur E Guedel (1883–1956) established himself as a pioneer in designing innovative equipment used to administer anesthesia in the USA. His textbook “Inhalation anesthesia” was published in 1937. He described and categorized physical signs that correlated with stages of ether anesthesia, which are described in major textbooks to this day.

Peter Safar (1924–2003) was instrumental in pioneering the science of cardiopulmonary resuscitation (CPR) (Safar 1959; Safar et al. 1959).

Virginia Apgar (1909–1974) developed a standardized scoring system for newborn babies that correlates with outcomes after birth and significantly reduced infant mortality throughout the world (Apgar et al. 1958).

In keeping with the evolution of the specialty of Anesthesiology as a science, original publications in peer-reviewed, scientific journals have become increasingly important in the current age. Based on the existing knowledge, the ASA and other subspecialty organizations have established evidence-based guidelines for good clinical practice, which are constantly updated.

Ethical Principles

As for other medical specialties, Anesthesiology is guided by the Hippocratic Oath, which is supplemented by the rules of the Declaration of Helsinki (1971). Anesthesiology is at the core of development of ethical principles in the practice of medicine and is intimately involved in developing guidelines related to end-of-life decisions. Henry Knowles Beecher, an anesthesiologist was instrumental in the implementation of federal

rules on human experimentation and informed consent by focusing world attention on unethical practices in medical experimentation (Best and Neuhauser 2010).

Key Values

The key value of the specialty of anesthesia is to alleviate human suffering and maintain life. This is done not only in the context of a patient undergoing surgery or painful procedures, but is also extended now to patients suffering from chronic pain as well as giving birth, and the acutely ill patient in intensive care settings.

Conceptualization

Nature/World

Nature is conceptualized as the biological and biochemical foundation of life on earth. The world comprises the material and interspersed space of the universe.

Human Being

The human being is considered a biological being equipped with a highly developed complex brain, and a complex functioning of organ systems giving them unique skills including emotions and abstract thinking, which differentiate them from the rest of the animal world.

Life and Death

Life is conceptualized as the presence of physical functions in biological systems. In the human body, it includes functioning of the cells in different organs. Death is considered the cessation of such physiological functions.

Reality

Reality is considered the physical world around us that humans can observe or measure with their senses.

Knowledge

Knowledge is understood to have an *objective* dimension, such that it is the *wisdom* that can be

transferred in a verbal or textual form from one person to the next. Knowledge builds up from one generation to the next. All knowledge has a scientific basis.

Truth

Truth is defined as the ultimate reality underlying facts and rules. Accordingly, truth is assumed to be absolute or universal, which humans can grasp only partially.

Perception

Perception is the *conscious sensation* of the forces and influences the external physical world exerts on living beings. Anesthesia, whether general or local, may disrupt or impair this perception.

Time

Time is the fundamental unit of ongoing change in the world. Humans can measure time *objectively* and perceive it owing to the changes observed in the surrounding environment. The perception of time can be affected by the influence of sedative or hypnotic drugs or when a patient is under anesthesia.

Consciousness

Consciousness is the responsiveness of subjects to any physical stimulus in the outside world. It can be graded in different levels of *sedation* ranging from minimal sedation to complete loss of consciousness. Consciousness can be altered by administration of medications. Under anesthesia, loss of consciousness is usually accompanied by amnesia.

Rationality/Reason

Rationality is a foundation of accountable and *responsible* human behavior and of understanding reason as ultimate authority. It is impaired under sedation and anesthesia.

Mystery

Often mystery is considered to be contradictory to modern medicine including Anesthesiology. In science, mystery is understood as potentially explainable after accumulation of adequate scientific knowledge.

Relevant Themes

Anesthesiology today is focused on meeting the challenges of modern surgical techniques. The role of novel drug administration techniques and target controlled infusion pumps are being explored. Research is continuing to develop drugs that can target specific areas of the brain with minimal side effects for the provision of anesthesia. New surgical techniques such as robotic surgeries and minimally invasive surgeries will make new demands on the anesthesiologist to tailor medications and techniques to suit the procedure.

Anicca (Pāli)

- [Impermanence \(Buddhist\)](#)

Anicca: Impermanence

Ven. Agganyani

German Vinaya Sangha Association (DBO) and
Centre for Buddhist Studies (CBS), Myanmar,
Bruckmuehl, Germany

Anicca (Pāḷi) or *anitya* (Sanskrit) is impermanence or transitoriness. According to Buddhist Abhidhamma, all phenomena, physical and mental, are momentary and transient only, they arise and dissolve. This impermanence is defined in ancient texts:

“Not existing before, they (the phenomena) arise.

Having arisen, they vanish forever.”

Anicca is not the slow change in things which one can observe. It is the constant, rapid arising, and immediate cessation of phenomena which can only be perceived by a well-trained, keen, and sharp mind in *vipassanā* meditation. According to the ancient Abhidhamma commentaries, arising and vanishing takes place at a tremendous rate of more than a 1,000 billion times per eyewink. In other words, the lifetime of phenomena is less than 1,000 billionth of a second.

In the Buddha’s teachings, the transience and constant renewal of phenomena is compared with dewdrops at sunrise, a bubble on water, a line drawn on water, or a lightning flash.

Anicca is one of the three universal characteristics of existence, of all conditioned phenomena (*saṅkhāra*), or in Abhidhamma terms, of all ultimate realities (*paramattha-dhamma*) except *Nibbāna*. In *vipassanā*, to penetrate and realize *anicca* of one’s meditation-object as well as of one’s observing mind (the subject), is said to be definitely necessary on the step-by-step stages of the insight knowledge (*vipassanā-ñāṇa*) which leads to disenchantment, equanimity, and final liberation of the mind.

The contemplation of impermanence (*aniccānupassanā*) is one of the three main methods in insight meditation. It discards the sign of perversion of permanence. *Nibbāna*

appears through the signless aspect and practice leads to signless emancipation (*animitta-vimokkha*) with faith (*saddhā*) as gateway to liberation.

Animal Theology and Ethics

Kurt Remele

Department of Catholic Theology,
Karl-Franzens-University Graz, Graz, Austria

Related Terms

[Cognitive ethology](#); [Interbeing](#)

Description

Animal Ethics is the conscious reflection on and the fundamental criticism of traditional ethical judgments and the prevailing, culturally validated moral beliefs in which (nonhuman) animals are dismissed from moral consideration or regarded as having little value compared with any kind of human interest. Animal Ethics challenges the anthropocentric, humanocentric, and instrumentalist view of animals held by Aristotelian (Aristotle, Thomas Aquinas) and Enlightenment philosophers (René Descartes, Immanuel Kant) and by many others. It contradicts those who regard animals merely as means to human ends, as machines, resources, commodities, and thereby reduce them to things to be

killed, eaten, and (ab)used arbitrarily. In contrast to humanocentric ethical concepts and to behaviorist psychology, but in accordance with the insights of contemporary *cognitive ethology* and neuroscience (Bekoff 2007), animal ethics proceeds from the scientifically substantiated assumption that (many) animals do have consciousness and emotions: Animals have mental experiences, they can perceive the things around them, they are able to think and to feel, they experience pleasure and pain, joy and fear, grief and various other feelings. Of course, it is important to remember that animals frequently use different senses than human beings do and that visual cues are not the only ones used in self-awareness.

The ability to experience pleasure and pain is commonly called *sentience*. Even though there are grey areas, because scientists cannot be absolutely certain which animals are sentient (and to what degree), it is safe to say that mammals and most other vertebrates (animals with a spinal column, i.e., mammals, birds, fish, reptiles, and amphibians) and even some invertebrates (e.g., octopuses), are able to feel pain and pleasure.

Animal ethics is based on the conviction that there is a link between sentience and the moral considerability or the moral status of a living creature. Animals' sentience therefore entails that how animals are treated by human beings really matters: Human actions must be evaluated as right or wrong, i.e., they are an ethical issue. The moral debate about animals at present mainly revolves around the following areas: animals being bred and killed for food, particularly under conditions that severely frustrate their natural needs (factory farming); animals used for medical experiments and cosmetic testing; breeding and killing animals for clothing (fur, leather); hunting, especially so-called sport or recreational hunting; the use of animals in education (biology, medical training, veterinary science), human entertainment (zoos, aquariums, circuses, horse and greyhound racing, bullfighting), military experiments and training; the welfare of companion animals (pets); genetic engineering and xenotransplantation (the transplantation of living

cells, tissues or organs from one species to another, e.g., from pigs to humans).

In contemporary Animal Ethics there are several ethical schools or theories that support the cause and the protection of animals: the utilitarian welfare theory, the rights theory, the feminist care tradition, and the generosity theory.

The utilitarian welfare theory goes back to Jeremy Bentham (1748–1832). Bentham demanded that human beings act in such a way as to maximize pleasure and minimize pain of both human beings and animals. Bentham was the mentor of Peter Singer, who in the 1970s initiated an animal liberation movement which has denounced the assumption of human superiority as arbitrary and “speciesist” and has compared it to the ideologies of racism and sexism (the term “speciesism” was coined by Richard Ryder, though). According to Singer (1995) all sentient beings, human or animal, have a basically equal claim to the recognition of their interests. Of course, as a utilitarian, Singer attaches great importance to the weighing of competing interests, not on moral and legal rights. In contrast, the animal rights theory (Regan 2004; Francione 2000) regards animals as intrinsically valuable, as “subjects of a life” who have certain individual rights which normally must not be infringed, even if it would benefit human beings to do otherwise. With regard to actual demands and concrete concerns, however, animal welfarists and animal rightists frequently agree. A large number of supporters of the contemporary animal protection-movement feel comfortable with a compromise position that regards animal rights as a long-term goal and an ideal state of affairs, yet accepts animal welfare measures as a short-time goal. This “new welfarism” proceeds on the assumption that there is some causal connection between cleaner and larger cages today and empty cages tomorrow. Both the feminist care tradition (Donovan and Adams 2007) and the generosity theory go beyond utilitarianism and animal rights: The former argues for attentiveness, sympathy, and emotional engagement in our relationships with animals and examines the links between species oppression and gender oppression (Carol Adams),

the latter contends that animals have an analogous status to that of children and therefore should be seen as having not equal claim but greater claim upon adult humans precisely because of their vulnerability and relative powerlessness. Its main proponent is the Anglican theologian Andrew Linzey.

It was also Linzey (1994) who first termed the phrase “Animal Theology.” Animal Theology is a theological approach that relates theology to contemporary debates about the status, the welfare and the rights of the (nonhuman) animals. It is not merely a study of animal ethics in the context of – in Linzey’s case – the Christian moral tradition (although, of course, it entails specific moral obligations), but rather a fundamental theology: Its content is the whole Christian doctrine read or reread from the perspective of contemporary science and its insight into animals’ minds and emotions and their consequent moral status. Animal Theology deals with three main areas of the traditional Christian doctrine: creation and the notion of human dominance, superiority or specialness; incarnation, the doctrine that affirms that God became human in the person of Jesus Christ; redemption, humanity’s reconciliation with God and its salvation by and in God through Jesus Christ. The traditional humanocentric bias of these fundamental Christian doctrines is reinterpreted by Linzey in a way that makes room for (nonhuman) animals: Human uniqueness is understood as a special responsibility to act not as the master but as the “servant species”; God’s becoming flesh in Christ affirms all flesh, both animal and human; animals are not excluded from God’s redemptive purposes, they are not without souls and will be granted immortality and supreme happiness after their earthly death.

Through his cooperation with Rabbi Dan Cohn-Sherbock, Linzey has developed his Animal Theology beyond the confines of the Christian tradition into a Judeo-Christian Animal Theology. An even more comprehensive notion of the term would suggest an examination and reinterpretation of all (major) religious traditions with regard to their theological understanding of animals, primarily Islam (as the third

Abrahamitic religion), Hinduism, Buddhism, and Jainism (all of which originated on the Indian subcontinent), Daoism, and Baha’i. In a comparative perspective, Hinduism, Buddhism, and especially Jainism seem to be more compassionate toward animals than the monotheistic religions. Yet a close theological scrutiny reveals that according to the tradition of these three religions it is frequently not the benefit of the animal that is the dominant factor for animal-friendly behavior, but the spiritual advancement of the practitioner or the belief that s/he himself/herself might be reborn as animal (reincarnation). Some contemporary interpretations of, e.g., Buddhism, however, emphasize the first Buddhist precept that prohibits all killing and calls for a vegetarian diet, and the Buddhist teachings of *interbeing* and of compassion toward all living beings (Thich Nhat Hanh, Phelps 2004).

Anthropic Principles

Neil Spurway
University of Glasgow, Glasgow, Scotland, UK

Description

Popular accounts of the history of science contend that the Copernican revolution diminished humanity's opinion of itself and that the Darwinian revolution completed our cutting down to size. From being the embodiment of *Imago Dei*, with dominion over the other inhabitants of the central component of the universe, Earth, the human species came to see itself as an accidental product of chance forces, precariously clinging to a brief existence on the surface of a trivial planet, orbiting an insignificant star near the edge of one among billions of galaxies. However, equating centrality with importance has little logic, and anyway few modern cosmologists would consider that the universe *has* a center. Moreover, the concept that life, even perhaps conscious life, arose only as the product of an immensely improbable sequence of accidents, has been challenged on strictly scientific grounds, quite independent of theological ones, by many thinkers in the past century. The term “anthropic principle(s)” seeks to encapsulate the common spirit of all these challenges. As coined, it referred directly to cosmological calculations, but the lead had been taken, early in the twentieth century, by biologists.

For an organism to survive, its environment must be fit for it just as much as it must be fit for that environment. Most discussions of evolution focus on the latter aspect, but the physiological chemist, Lawrence Henderson, gave detailed and often quantitative recognition to the reciprocity in *The Fitness of the Environment* (1913) and later writings. Among Henderson's most telling examples are the exceptional properties of water – e.g., that its solid state is less dense than its liquid one, with the consequence that aquatic life can continue at the bottom of lakes whose surfaces are frozen. A remarkable range of other special properties is cited, with modern values, in Barrow and Tipler (1986).

Such thinking was taken forward by some other biologists, notably George Wald, two generations after Henderson; among his emphases were the extraordinary properties of chlorophyll. Nonetheless, the pioneering steps which followed Henderson's were taken by cosmologists. Among them, beginning in the 1930s and increasingly since the 1950s, recognition of an apparent “fine-tuning” of the universe for life has emerged. The features considered during this phase were on a very large scale. Most basic of all, the very age and consequent size of our universe, far from demonstrating our insignificance, became recognized as essential if stars were to have had opportunity to host the nuclear syntheses which produce carbon, nitrogen, oxygen, and phosphorus – elements at the core of life as we know it. That recognition seems to have been voiced first by J.G. Whitrow in the 1950s, but of course it depended on the earlier redshift observations of Edwin Hubble and the imaginative perception of George Lemaitre, out of which has come the modern acceptance of a universe expanding in a finite time from an initial singularity.

The concept of an *anthropic principle* was introduced in the 1970s by the cosmologist Brandon Carter (Leslie 1990), reflecting on a group of “large-number coincidences” originally noted 40 years earlier by the physicist P.A.M. Dirac. These (enormously) large numbers, extremely esoteric to the layman, were the dimensionless ratios of various physical constants, and the coincidence was that these ratios

seemed constrained to lie very close to $(10^{40})^n$, where $n = -1, 0, 1$ or 2 . The most easily stated of the figures is an instance of $n = 2$: it is the ratio of the mass of the observable universe to that of the proton or neutron, a ratio which is $\sim 10^{80}$. The additional realization during 1950–1975, associated particularly with John Wheeler, R.H. Dicke, and thence with Carter, was that Dirac’s coincidences themselves “were not random but conditioned by biological factors” – had the ratios not been close to those found, there would have been no cosmologists to observe them.

The phrase “anthropic principle” sought to express this recognition, and Carter formulated it in two ways (Barrow and Tipler 1986; Leslie 1990). The *weak anthropic principle* (WAP) merely noted the inevitability just expressed. This represents the situation as an example of a “selection effect” – the only kind of universe which can ever be observed is one which creates its own observers. Though inevitable, this is not trite. On the contrary, it indicates that many detailed aspects of the world’s makeup, which on other grounds would seem to have an immense range of possible values, could in fact have varied only a very little from those we actually find if we were to exist and observe them.

Aspects of fine-tuning recognized since Dirac include the perception that a term in Einstein’s extended formulation of general relativity, the “cosmological constant,” which influences the course of universal expansion, must be and is extraordinarily small – so small as to suggest that it may actually be zero – though values ranging over many orders of magnitude seem in principle possible. A second aspect is that the ratio of the forces of attraction and repulsion between nuclear particles (the “strong” and electromagnetic forces) could have differed only fractionally from those we observe if atoms were to form. A third is that the amount by which a neutron’s mass exceeds that of a proton must also be very small if anything like the chemistry we associate with life is to be possible. However, it is not enough to list the low probabilities that each individual factor would be in the right range for life to result because the probability of *all* of them being so is the product of the

individual estimates. To appreciate the strength of this point, consider that if a mere six factors would each permit life in as much as a tenth of its possible range, the overall probability of life being possible would be $1:10^6$ – one in a million. Actually, well over 20 factors have been identified, and many of the individual probability estimates are a great deal lower than one in ten. Indeed, one parameter has recently been estimated as having only one chance in 10^{120} of being right for galaxy formation, and therefore for life, were its value to have been determined by random influences (Davies 2006). Many cosmologists have thus concluded that the universe is enigmatically fit for life – “uncannily” so in Paul Davies’ phrase – or, in the words of the late Fred Hoyle, “a put-up job.”

Carter, apparently sensing this trend well before many of the calculations cited here, proposed a second and “strong” anthropic principle (SAP) that *the Universe must be such as to admit creation of observers within it at some stage in its history*. “Must” is ambiguous: deduction or imperative? As the deduction would merely restate the WAP, an imperative is normally presumed (Barrow and Tipler (1986); Davies 2006; c.f. Leslie 1990). This is a far more metaphysical statement, and the nature of the imperative it adduces is scientifically obscure. Its theological scope, however, is obvious.

Several developments of the SAP have subsequently been proposed: two will be mentioned. Wheeler, reflecting subjectivist interpretations of quantum theory, suggested a “participatory” anthropic principle (PAP) evocative of Bishop Berkeley: *observers are necessary to bring the universe into being*. The alternative, “many worlds” interpretation of quantum mechanics, first suggested by Hugh Everett and considered by Carter, leads to the proposition that there are countless parallel, independent universes, each with a random distribution of properties, one of which has happened to produce us. The overall complex has lately acquired the name “multiverse.”

The scientific value of positing a myriad, perhaps an infinity, of universes which we can, by definition, never know has been philosophically

challenged. Theists suspect that it is the last recourse of minds constitutionally incapable of accepting the idea of a creator – which seems to the theists immensely simpler and more satisfying. However, they must concede that a creator is not a scientific concept either!

Theistic implications apart, most commentators regard the family of anthropic principles as modern versions of the classical and medieval arguments from design (Manson 2003). It is questionable, however, whether this is a proper perspective on the WAP: no true design argument consists in pointing out the inevitable. By contrast, the SAP, as interpreted here and in Barrow & Tipler (1986) and Davies (2006), is clearly in the category, and a case can be made for considering the PAP as in it too. The multiverse concept offers a determinedly contrary view.

One final point: The physical and chemical considerations adduced in this field of theorizing combine to make a very strong case indeed for concluding that the universe we inhabit is predisposed to harbor *life*. But life is not consciousness: to move from one to the other is to make a metaphysical leap whose magnitude can scarcely be exaggerated. Yet every proposed anthropic principle refers to observers and so implies consciousness. This point was doubtless, not lost on Brandon Carter, though he did not expressly acknowledge it; it should not be lost on us.

[Anthropology in the Muslim world](#)

Muslim/Islamic anthropology is not a fully developed social science discipline/subdiscipline in either Muslim or non-Muslim academic contexts. Articulated and advocated for in varying ways, by a range of authors, including Said Mohamed Mauroof (1981), Akbar S. Ahmed (1986), and Merryl Wyn Davies (1988), Muslim/Islamic anthropology remains at the level of a proposition. Common to such proposals are critiques of the epistemological assumptions, prejudices, and sociopolitical agendas that underlie Western (Euro-American) social science knowledge production in general and anthropological knowledge production in particular; use of concepts and ideas from the Qur'an, other foundational texts, and the works of classical Islamic scholars to construct an Islamic study of man; and appeals to Muslim scholars to advance an Islamic worldview and ethos through their investigations of human social and cultural life.

This entry surveys the proposals for Muslim/Islamic anthropology by the above-mentioned authors and some criticisms put forward about their ideas from scholars working in the discipline of Western anthropology.

Said Mohamed Mauroof's, "Elements for an Islamic Anthropology," is part of a volume on *Social and Natural Sciences: The Islamic Perspective*. Mauroof's main concern is with importing (wholesale) Euro-American anthropology and its accompanying assumptions and epistemological frameworks into institutions of higher education institutions in Muslim contexts (1:117ff). He argues that Euro-American anthropology has an epistemology, intellectual history,

goals, and values that are rooted in Western ideological systems that are influenced by Christianity. Islam has different sources, orientations, and approaches. For example, Mauroof states that "the World of Islam has known no parallel to the intense *religion vs. science* debates so characteristic of Euro-America" (1:136). He proposes that Muslims develop Islamic anthropology on the basis of Islamic sources such as the Qur'an and *hadith*, as well as the curricula, methods, and scholars of Islam's classical scholastic tradition. The Qur'an is primary for anthropology because it contains a theory of human history and "a conception of humankind" (1:123). In Mauroof view, the Qur'an also addresses issues of human diversity and the "nature of groups" and engages in a discussion about "natural bonds of mutual obligation" (1:123). It also contains appropriate theoretical and axiological categories for anthropological reflection. Most importantly, the Qur'an calls upon mankind to undertake "a scientific approach to the study of history" (1: 123). Thus, for Mauroof, there is no conflict between the God's Word and the social scientific study of man. In this regard, his views echo those of Isma'il R. Al-Faruqi, the coeditor and a contributor to the volume, who proposes that an Islamization of the social sciences would engender a "discovery and understanding of the divine pattern in human affairs," as God articulates in the Qur'an (1:16–18). For Mauroof, the scholarly efforts of classical Muslim scholars such as Ibn Khaldun (1332–1406), al-Biruni (973–1048), and Ibn Battuta (1304–1368/9) exemplify the best efforts Muslims have made in terms of the study of man. While not anthropologists proper, the texts of these classical scholars contain "proto-anthropological" strands. Indeed, for Mauroof, the "descriptive, analytic or comparative investigation of man" was part of the Islamic classical curriculum and should be considered part of contemporary teaching and learning. Mauroof also suggests that Islamic anthropology extends beyond social and cultural issues to biological anthropology and archaeology. His interpretation of the Qur'an's statements about history and human life are used to support these views. In sum, for Mauroof, it is

the introspective examination and use of this range of Islamic sources that can produce an anthropology that is distinctively Islamic in form, content, and intention.

Akbar S. Ahmed develops his fullest conception of Islamic anthropology in *Toward Islamic Anthropology: Definition, Dogma and Directions* (1986), a work written as part of “Islamization of Knowledge” series directed by Isma’il R. Al-Faruqi. From the outset, Ahmed states that his proposal “defends a metaphysical position, advances an ideological argument and serves a moral cause,” namely, Islam (2:13). Nonetheless, he argues, there is merit in developing Islamic anthropology in so far as it can seriously challenge the presuppositions and conclusions about Islam and Muslim societies that continue to be articulated by Western anthropologists and conduct studies that ultimately “illuminate God’s plan/path for humankind” (2:57–58). Thus, like Mauroof, Ahmed, who frequently refers in his essay to the sociologist Ali Shariati (1933–1977), stresses that in Islam, religious beliefs do not conflict with an anthropological study of Islam. Ahmed’s main concerns are with the prejudices and ignorance about Islam and Muslims that have proliferated in Western anthropology since its inception. Among these misunderstandings is the idea that there are “many Islams,” a view forwarded by A. H. El Zein (1977), a Muslim anthropologist working from within the Western anthropological tradition. In this regard, Ahmed categorically states that “there can only be one Islam” and therefore “we must attempt to place the multitude of Muslim societies within the framework of one universal Islam” (2:58). Ahmed argues that contemporary social anthropology is a branch of empirical, observational science focused on the study of man that developed in the nineteenth century as part of the European colonial project: “anthropology is, if not a child, a creation of the West and more specifically Western imperialism” (2:56). Its flaws lie in the ethnocentrism, orientalism, arrogance, and hostility toward the “other” of some of its practitioners. By contrast, Ahmed defines Islamic anthropology as “the study of Muslim groups by scholars

(Muslims and non-Muslims) committed to the universalistic principles of Islam – humanity, knowledge, tolerance – relating to macro village tribal studies in particular to the larger historical and ideological frames of Islam” (2:56). Such a project can serve to dispel some of the myths generated about Islam and Muslims and provide Muslims a way to examine their own history and societies. Thus, among the projects Ahmed proposes are a sociological account of the life the Prophet Muhammad and studies comparing “major social categories (e.g., peasants, tribes and cities) which would help us better understand and reach conclusions regarding Muslim society and its immediate contemporary problems” (2:66).

Merryl Wyn Davies’s book-length monograph *Knowing One Another, Shaping an Islamic Anthropology* (1988) defines Islamic anthropology as “the study of mankind in society from the premises and according to the conceptual orientations of Islam” (3:82) and “a social science, concerned with studying mankind in its social communal relations in the diversity of social and cultural settings that exist around the world today and have existed in past. The focus of its attention is human action, its diversity of form and institutionalization; it seeks to understand the principles that order, organize and give it meaning” (3:113). Like Mauroof and Ahmed, Wyn Davies locates the building blocks of Islamic anthropology in the Qur’an. But she goes much further in elaborating upon a number of Qur’anic concepts such as *nafs* (soul, the agentive force that binds and permeates humanity), *khilafa* (man’s role as vice-regent of the earth), and *tawhid* (unity of Being). She draws upon these concepts in a systematic manner to develop a rationale and impetus for her endeavor and a conceptual framework for her inquiry. For Wyn Davies, it is essentially the idea of “God’s purposeful ordered creation” through which one can undertake Islamic anthropology (3:86). That is, since all of creation, including mankind, is compelled to know God through His creation, the holistic study of humanity within creation is also an imperative. Wyn Davies elaborates upon the appropriate subjects of study for Islamic

anthropology. Chief among these is *umma*, “a range of units of community formation” that can refer to “a people, a society, a nation, a tribe, a culture, or a multi-social, multi-cultural community” (3:128). Wyn Davies goes further adding that implicit in the conception of *umma* is the “idea of diversity of communities” (3:128). Hence, to “know one another,” a Qur’anic imperative, is the logical outcome of an anthropological investigation, particularly in the context of undertaking ethnographic fieldwork, and provides further evidence of the Qur’anic basis for the study of humanity. Ultimately, Wyn Davies calls for Islamic anthropology to be renamed ‘*ilm al-‘umran*, the total science of social organization/civilization/culture elaborated upon by Ibn Khaldun. Here, the use of ‘*ilm* “firmly establishes the conceptual foundations as those of Islam, and therefore conditions the mind set of the Muslim scholar undertaking this branch of knowledge” (3:161).

These propositions have drawn a series of criticisms from anthropologists working on anthropology of Islam/Muslims, an emerging field in Western (Euro-American) anthropology. Scholars such as Richard Tapper (1995), Daniel Martin Varisco (2004), and Gabriele Marranci (2008) have argued, in different ways, that proposals advocating for Muslim/Islamic anthropology are not “scientifically objective” and are “theologically deterministic” (7:48). They question the extent to which such proposals can accommodate diverse expressions of Islam and plurality of readings of the Qur’an that are made by Muslims themselves; for example, they ask who decides which concepts and Islamic ideals are to be adopted into this science? To this, one could add that the proposals do not make clear the hermeneutics used to read and interpret the Qur’an, processes that are elaborated on at length in the classical Islamic tradition. Such proposals also have little new to offer anthropology and social science and simply replicate Western anthropological methods and theoretical concepts, often under the guise of an Islamic/Arabic/Qur’anic vocabulary (5:190).

While a number of these criticisms remain unanswered, it may be worthwhile noting that

scholars working in the anthropology of Islam/Muslims have presented critical examinations of knowledge production about Islam and Muslims in anthropology, as well as methodological propositions that aim to examine the epistemological frameworks from within which Muslim social actors express themselves (5, 6, 8, 9, 10). These studies are taking place at a time when Western anthropologists are exploring the possibilities afforded by the notion of “world anthropologies,” examining the whole arena of science and responding to the increasing presence of Islam and Muslim societies on the world stage (Hirji 2010). There may be the potential in these trends to renew a dialogue about Muslim/Islamic anthropology.

Anthropomorphism

Stewart Elliott Guthrie

Fordham University, New York, NY, USA

Personification

Anthropomorphism may be defined as the interpretation of nonhuman things and events in terms of human characteristics. For example, we may perceive a stuck drawer as stubborn, think that a plague is a message, or see an upright garbage bag as a person. The term stems from the Greek *anthropos* (“human”) and *morphe* (“form”). Originally it meant understanding gods in terms of human physical or mental features, but by the 1800s it also meant a broader phenomenon that occurs not only in religion but also throughout secular thought and action. It is common in daily life, in the arts, and even in the sciences. Much of it is unconscious.

Following Francis Bacon (1561–1626), who noted that purposes and goals characterize humans but not nature in general, most commentators have said that anthropomorphism obstructs better understandings of the world. Nonetheless, it is persistent and indeed universal.

Humans everywhere have, for example, understood deities as humanlike, with such qualities as anger, vanity, and affection, and often with humanlike physical form as well (Harvey 1995). Even deities that look like animals or, that are invisible, are conceived as understanding prayer, offerings, and other human communications. Writers have noted such anthropomorphism in religion at least since the time of Xenophanes (c. 560 to c. 478 B.C.E.), who criticized conceptions of

humanlike gods. Theologians have sought to reduce religious anthropomorphism, but most say that we cannot eliminate it without eliminating religion, because we cannot relate to deities totally unlike ourselves. Deities must have humanlike language and symbolic behavior, for example, or we could not interact with them. Indeed, a classic theory of religion holds that religion itself is best understood as anthropomorphism (Guthrie 1993; Harvey 1995; Hume 1957).

As noted, anthropomorphism is not restricted to religion, but pervades secular thought and action as well, so that human features seem to appear throughout nature and even among artifacts (Anthropomorphism.org 2008; Caporael and Hayes 1997; Epley et al. 2007; Guthrie 1993, 1997, 2007). Stars, storms, oceans, mountains, the Sun and Moon, and the Earth itself are seen as alive and active. Similarly, humans everywhere have seen implements (swords and spears in antiquity, for example, and cars and computers at present) as volitional. In literature and graphic art, such depiction is often called personification, especially when the subject is an abstraction (such as Death or Liberty).

Anthropomorphism is common in science also, though often criticized there. For example, Isaac Newton (1642–1727) used love and hate, or attraction and repulsion, in his physics. Astronomers at first thought pulsar radio waves were messages. Neurologists speak of brain cells “talking” with each other; and Charles Darwin (1809–1882) said that Nature sought constantly to improve her creatures. (That some of these claims may be called metaphorical makes no difference, since metaphor is basic to all domains of human thought, including science.)

Nonetheless, most scientists see anthropomorphism as subverting good science, and they strive to avoid it. In the history of science, anthropomorphism has therefore diminished steadily and significantly. In religion, in contrast, anthropomorphism apparently cannot be eliminated and arguably is central. Thus, the different degree of

anthropomorphism found in science and in religion appears as a major dimension of contrast between the two.

If, as most scientists hold, anthropomorphism is a mistake, why is it so common? Established explanations are of two kinds, which may be called the familiarity and the comfort theories (Guthrie 1993). The familiarity theory, advanced by the philosopher David Hume (1711–1776) and others, is that our motives are intellectual: We wish to understand the world, which otherwise is uncertain and mysterious, and we do so by using the model most familiar to us, that of ourselves (Hume 1957). This theory is useful, but fails to show why humans also anthropomorphize things and events that are themselves familiar, such as the behavior of cars and computers, or why we see faces in accidental patterns such as those of clouds.

The second theory, held by Sigmund Freud (1856–1939) and others, is that our motive is emotional: to make the world less threatening. This theory is useful as well, but does not explain why we posit humanlike yet frightening features in the world, as when we mistake the night-time sound of a door closed by the wind for the sound of a burglar.

A third explanation, more recent and more general, agrees with Hume that we live in a chronically uncertain world that we need to interpret. This newer view differs, however, on the reason why we use humanlike models to do so. It is not because they are familiar or reassuring, but because they represent the most important possibility. If an actual human, a human message, or a human trace is present, we need to know it, since humans are uniquely powerful and important.

However, because our perceptual worlds are always uncertain and because humans may operate from behind the scenes, we can never be sure that they are not present. As the psychologist and historian of art Ernst Gombrich (1909–2001) notes, perception is interpretation and hence a bet. According to the third theory, those bets that may give the most information are the most valuable, and these usually involve humans. Therefore, we are unconsciously

disposed to see and hear the world in terms of human qualities.

Indeed, our evolved perceptual strategy is much like that of Pascal's Wager: better safe than sorry. When in doubt about what an event or something is, we tend to assume that it is human. If we are right, we are rewarded by being prepared, and if wrong, we lose little.

Analogy and metaphor, among other forms of abstraction and pattern recognition, underlie much of human thought and action. Through them, we often see humanlike qualities even where we see neither actual humans nor actual traces, as when we see "design" in organisms or see epidemics as punishments. Nevertheless, the interpretive impulse leading to anthropomorphism is not to make the world humanlike. Instead, it is to find whatever humans, or their messages or traces, actually are present. In a world of perceptual uncertainty, we inevitably overestimate these.

Our better-safe-than-sorry strategic response to uncertainty and our resulting anthropomorphism appear deeply rooted in our neurology (Anthropomorphism.org 2008; Farah and Heberlein 2007) and, in turn, in evolution. Hence it is unsurprising that our perceptual strategy is not unique to humans but appears also in other animals which, like us, seem on a hair trigger to perceive more animacy in the world than actually exists (Guthrie 2002; Foster and Kokko 2008).

Under any of the three theories discussed, when we first see something (e.g., a shadow in an alley) as human or humanlike but later see it as something nonhuman, we may call our earlier interpretation anthropomorphism. And under any of the three, anthropomorphism may be described as a category of interpretations retrospectively seen as mistaken.

Apocalypticism

Robert M. Geraci

Associate Professor of Religious Studies,
Manhattan College, Riverdale, NY, USA

A social system reflective of or emergent from apocalyptic texts, such as the biblical books of Daniel and Revelation. It is characterized by four chief features: (1) a dualistic view of the world in which good and evil contest against one another, (2) an experience of alienation caused by the present circumstances in which evil is apparently ascendant, (3) the expectation that a transcendent guarantor (usually a god) will soon rectify the alienating circumstances by creating a new and glorious world, and (4) the belief that humankind will take on glorious new bodies with which to occupy the transcendent new world. Apocalyptic beliefs have influenced science at least since the medieval period, where they encouraged European thinkers to develop technologies that could be used in war with the Antichrist. In the twentieth century, apocalyptic expectations have been relevant to a wide array of technological fields, including robotics and artificial intelligence.

Apodosis

- Eschatology

Apophatic and Cataphatic

Catharina Stenqvist

Centre for Theology and Religious Studies,
Lund University, Lund, Sweden

Apophatic theology or *negative theology* concerns the possibility and non-possibility of achieving knowledge of the divine. Apophatic

theology claims an absolute difference between the human being and the divine. This difference makes the human being incapable to employ either her natural faculties or her senses in her effort to achieving knowledge of the divine. In virtue of realizing this non-possibility, she has to enter into a dimension of non-conceptuality through which she understands the discrepancy between herself and the divine. She enters “the cloud of unknowing.” Hereby she gains the wisdom that the divine is beyond comprehension and is to be perceived by renouncing her natural faculties. The divine is commonly described as “hidden” and “secret,” and the human being perceives the divine through a mental darkness. Apophatic theology employs the idea of a qualitative difference, a difference in kind, between the human being and the divine.

Cataphatic theology or *positive theology* claims a similarity between the human being and the divine, which makes it possible to achieve knowledge of the divine. The knowledge is gained through using the natural faculties such as the five senses and reason. By using an analogical thinking, that is, making a comparison between the human being and the divine, it is possible to achieve a partial understanding and knowledge of the divine. Cataphatic theology employs the idea of a quantitative difference, a difference in degree, between the human being and the divine.

Applied Mathematics (Mathematical Physics, Discrete Mathematics, Operations Research)

Luis Vázquez

Departamento de Matemática Aplicada, Facultad de Informática, Universidad Complutense de Madrid, Madrid, Spain

Related Terms

[Mathematics and empirical sciences](#)

Description

Applied Mathematics is a discipline of Mathematics which deals with the application of Mathematics to understand and to solve the problems which appear in the investigation of the Physical World (Science, Technology, and Engineering) and Human Enterprise (Sociology, Business, and Commerce). This discipline also includes the studies and developments of the mathematical areas useful in the past to solve real world problems or promising for present problems.

Historically, Applied Mathematics has been largely reduced to ordinary and partial differential equations, continuous mechanics, numerical methods, and the calculus of variations. The numerical methods combined with the computers allow finding approximate solutions for explicit mathematical problems given, for instance, in terms of differential and/or variational equations when the analytic solutions are not available or cannot be obtained. Initially, the significant part of Applied Mathematics relied on the problems arising from physics and with the broad range from classical to quantum systems. On the other hand, Applied Mathematics has grown to include a large variety of areas or subdisciplines which take into account, for instance, the contributions of the algebra to particle physics as well as to the study of the genome. We will consider three of such subdisciplines: Mathematical Physics, Discrete Mathematics, and Operations Research.

In each case, we have to consider four cornerstones as the ground support of the Applied Mathematics:

- *Data* obtained from the observation and experimentation. They are the primary reference in the study of any problem. The Data Mining is a correlated area with a strong identity in its own.
- *Algorithms* which are used to analyze data and models. In many cases, we only have the data while in others we have data and equations. When we have equations, there is a good instrument of reference to study and to combine with the data. At the same time, we have to develop numerical methods to approximate the solutions of such equations.
- *Theories and Models* include the theories of Pure Mathematics and they are used to analyze the data and the ideas. The Applied Mathematics provides a basic ground test for ideas in which the strength of competing theories can be measured.
- *Computers* as instruments to implement the algorithms and carry out large and massive computations, which allow exploring the solutions of the models in unthinkable and unexpected regions.

Mathematical Physics

The objective of the Mathematical Physics is the application of the mathematics to problems in physics and the development of mathematical methods appropriate for such applications and for the formulation of the physical theories.

The theory of differential equations is perhaps the most closely associated with Mathematical Physics. This theory is related to many applications as celestial mechanics, acoustics, elasticity theory, thermodynamics, electromagnetism, hydrodynamics, and aerodynamics. On the other hand, the development of the linear algebra, the spectral theory of operators, and the functional analysis are the mathematical basis of the quantum mechanics and the theory of the atomic spectra. The group theory also played an important role in quantum field theory as well as in differential geometry, which turns out to be relevant for special and general theories of relativity. In the

mathematical description of cosmological and quantum field theory phenomena, the topology is playing an important role. Other separate field of the mathematical physics is the statistical mechanics, which is closely related to the mathematical ergodic theory and some parts of the probability theory.

Sometimes the Mathematical physics denotes the research addressed to study and to solve problems motivated by physics within a mathematically rigorous framework. In this sense, the Mathematical Physics covers a very broad area of topics with the common feature that they combine pure mathematics and physics. Related to the Mathematical Physics we have the Theoretical Physics which emphasizes the links to observations and experimental physics and which requires using heuristic, intuitive, and approximate arguments. We can say that rigorous mathematical physics is closer to mathematics and theoretical physics is closer to physics.

The field of Mathematical Physics is basically concentrated in four main areas:

- Quantum Field Theory devoted to precise construction of models
- Statistical Mechanics especially concentrated in the theory of phase transitions
- Nonrelativistic Quantum Mechanics including the connections to atomic and molecular physics
- Quantum Information Theory

Discrete Mathematics

The Discrete Mathematics is the branch of Mathematics that studies the mathematical structures that are fundamentally discrete rather than continuous. The discrete objects can often be enumerated by integers. In a formal framework, the Discrete Mathematics deals with countable sets, which have the same cardinality as subsets of the natural numbers. In this context, the set of objects studied in discrete mathematics can be finite or infinite. The term Finite Mathematics is sometimes applied to the parts of the field of discrete mathematics that deals with finite sets. The Discrete Mathematics excludes the Calculus and Analysis of the continuous mathematics

which is the branch of the mathematics dealing with objects that can vary smoothly. On the other hand, the analytic methods from continuous mathematics are often employed as well in Discrete Mathematics. This is the case of Discrete Calculus and Discrete Analysis, which cover the discrete version of concepts in continuous mathematics as the examples of difference equations, discrete Fourier transforms, and discrete probability distributions.

The development of the computer increased the research in Discrete Mathematics. The computers operate in discrete steps and store data in discrete bits. The concepts and notations from Discrete Mathematics are useful in the study and description of objects and problems in different branches of computer science, for instance, programming languages, software development, algorithms, and cryptography. Reciprocally, due to the computer we can apply ideas from Discrete Mathematics to real world problems as in Operations Research.

The history of Discrete Mathematics is involved with grand challenging problems. In Graph Theory, much research was originated to prove the famous *Four Color Theorem: All maps could be colored with only four colors*. This was stated in 1852 and proved by Kenneth Appel and Wolfgang Haken in 1976, by using substantial computer assistance.

In Logic, the second and tenth problems of David Hilbert's list of open problems presented in 1900. The second problem was to prove that the axioms of arithmetic are consistent. In 1931, Gödel showed that this was not possible, at least not with arithmetic itself. Concerning the tenth problem, it was proved in 1970 by Yuri Matiyasevich that we cannot determine whether a given polynomial Diophantine equation with integer coefficients has an integer solution.

World War II was the driving force for the advances in cryptography and theoretical computer science. The Computational Geometry is a basic component of the computer graphics incorporated into modern video games and computer-aided design tools. Other fields of Discrete Mathematics are very relevant to solve challenging problems in Bioinformatics

associated to understand the tree of life. This is the case of Combinatory and Graph theory.

We can summarize some of the relevant topics in Discrete Mathematics:

- Information theory
- Mathematical logic
- Set theory
- Combinatory: Discrete probability theory
- Graph theory
- Number theory
- Abstract algebra
- Discrete and computational geometry
- Discretization: Finite differences

There is special relevance of the Discretization which concerns the process of approximating continuous models and equations by discrete systems. The difference equations are similar to differential equations, since they replace the differentiation by incremental differences. That allows approximating the solutions of equations where the analytical methods cannot be applied. In this approach, we have different important issues as the relation between the discrete and the continuous solutions. It is high desirable that the discrete approach preserve the main features of the underlying continuous system, otherwise the numerical solution could not have nothing to do with the continuous solution.

Operations Research

The Operations Research is a discipline that studies the application of advanced analytical methods to help to make the better scenario for the decisions. This provides techniques for solving practical problems in business and other fields such the allocation of resources to maximize profit or the schedule project activities to minimize the risk. These techniques include areas of optimization as the linear programming, the queuing and scheduling theories, as well as the network theory. On the other hand, the Operations Research also includes continuous topics such as continuous-time Markov process, continuous-time martingales, and continuous and hybrid control theory.

Historically, and as a formal discipline, the Operations Research originated during World War II as a consequence to define strategies

to reduce the ships and airplanes losses in the different kind of actions. After the war, the operational research has expanded to be applied in business, industry, and society. It was extended to analyze equipment procurement, training, logistics, and infrastructure. Some of the addressed relevant problems are the following:

- **Network Organization:** For instance, optimize the network telecommunications in order to guarantee the quality of the service
- **Routing:** To determine the routes of transportation in order to minimize the costs and the time of transportation
- **Project Planning:** To identify the processes that affect the overall duration of the project
- **Allocation and Assignment:** To find the appropriate distribution of tasks, problems, and resources in order to optimize the project

The business use of the Operations Research was defined by Stafford Beer in 1967 as the Management Science which becomes an interdisciplinary branch of applied mathematics. It is devoted to optimal decision planning with strong links with economics, business, and engineering. The Management Sciences help businesses to carry out their goals by using the scientific methods of operational research.

Self-Identification

Science

Applied Mathematics is deeply related to the observation and experiment because the main objective is to quantify and solve, through the modeling, the problems which arise in the study of the physical world and the human enterprise. In this context, the studies of Applied Mathematics allow to make predictions about other regions of the involved parameters where either we do not have complete information and/or experimental data. That shows the relevance of the experiments. Moreover, the beauty of the Mathematical power lies in the possibility to connect different kinds of problems through the similar mathematical structures used to study them.

Religion

The oldest records about mathematics show it appears as the answer to practical problems in agriculture, astronomy, business, and industry. Such evidences are found in Egypt, Mesopotamia, India, and China. Later on, the Greek contributions introduced a deep change in the nature and approach to mathematics. Initially, the knowledge of the mathematical developments was associated to the religious environment of the temples. For instance, in old Greece some groups devoted to the study of different areas as Algebra, Analysis, and Geometry were tied to certain rules of life, which could be understood as practitioners of a religion.

The Applied Mathematics covers the development of new mathematical scenarios and instruments that can be applied to understand practical problems as well as the application of such techniques. We can say that the Applied Mathematics cannot be considered as a religion but as an approach to understand the reality, which is also an objective of the religion. A better approach to describe the reality implies better knowledge and more possibilities to interact with it.

Characteristics

The Applied Mathematics is transdisciplinary in the sense that the same approach of modeling and simulation can be applied to problems with very different experimental context in the Physical World and the Human Enterprise. On the other hand, the Applied Mathematics represents an interface between the world of the problems to be solved and the world of the computers that have to be used when the nature of the associated simulations and computations are very large and complex.

Relevance to Science and Religion

The Science and Religion are two fundamental dimensions of the human being related to the activity of the human brain. On the other hand, the Applied Mathematics as a part of the Science

activity has a great impact in technology for modeling and simulation. There is a large range and variety of applications of mathematics in industry and government, by involving fields as communication and optimization theories, design, medical diagnosis, development of financial products, as well as network management and weather prediction.

Sources of Authority

The authority relies on different sources as the publication of the results in peer-reviewed papers; and the nature of the solved problems of the physical world and human enterprise. Historically, the authority of the Applied Mathematics is the same of the Mathematics in general: the mathematicians from Egypt and Mesopotamia to our days.

Ethical Principles

The ethical principles are basically the disclosure of the designed mathematical methods and numerical algorithms such that they can be repeated and confirmed.

Key Values

The Mathematics and, in particular, the Applied Mathematics is a basic tool to educate the mind to design the mathematical and algorithmic strategy to approach the solutions of problems where the solution is unknown. To compare the solutions obtained with different strategies is fundamental to ensure the reliability of the solution. On the other hand, such strategies have to reproduce the available qualitative and quantitative knowledge of the system.

Conceptualization

Nature/World

The Nature is the Energy and Matter with their Physical and Biological manifestations that the Applied Mathematics tries to understand. The

World is the Nature plus the Human Enterprise through the Science, Technology, Engineering, Business and Commerce.

Human Being

The Mathematics and, in particular, the Applied Mathematics is a creation of the human being who starts to construct it as a response to practical needs in agriculture, business and industry.

Life and Death

The life in Applied Mathematics is associated to the possibility of exercise the singular capacities of the human brain activity. When such possibility is not anymore possible we have the death from the mathematical point of view.

Reality

The Reality is the Physical and Biological together with the Human Enterprise and the World of the abstract structures created by the human brain.

Knowledge

The knowledge associated to the Applied Mathematics is the wide range of studies with significant application in the empirical sciences.

Truth

The Applied Mathematics models are an approximation to the Reality under the context of the Mathematical Logic and Set Theory, which are in the foundations of Mathematics.

Perception

The perception of the Reality is associated to the model context. An important feature is that the models offer the possibility to enlarge the panoramic view of the studied problem and to find possible unexpected connections with other problems.

Time

The time is the fourth dimension of the Reality and plays a key role in the modeling of the phenomena that evolves in time. The time scales are fundamental to understand the dynamics of many systems. Precisely, the competition among the different scales of time and/or space is on the basis of the chaotic behaviors.

Consciousness

The consciousness is associated to a high mental state that in the framework of the panoramic view provided by Applied Mathematics could correspond to the whole possible set of relations with other areas associated to the studied problem.

Rationality/Reason

The rationality is the basic capability of the human brain to clarify the foundations of Mathematics, and the Applied Mathematics, through the Mathematical Logic and the Set Theory. Applied Mathematics is one way to translate our perceptions into rational and reasonable premises.

Mystery

The mystery is associated to the lack of knowledge and appropriated mathematical instruments to study a given problem. Any time we make a progress to model and understand a problem, we increase our knowledge in the broad sense. Sometimes the kind of mystery associated to certain codes or algorithms is related to the cost of their development and his restricted use. The fact of the existence of Mathematics confirms that there is a mystery we need to quantify and to explore. Maybe we can say that if Religion is "The Question," Mathematics (Science) is "The Answer."

Relevant Themes

The Applied Mathematics is understood as the use of Mathematics to solve and quantify the problems which arise in the investigation of the physical world and human enterprise. In this context, the Applied Mathematics has grown to include other issues associated to other areas as biomathematics, cryptography, economics, scientific computation, social networks, and finances among others. These areas increase every day the impact in our lives.

Inactivity

Apraxias are deficits of higher motor behavior that are not primarily caused by elementary deficits of the sensorimotor system such as paresis, ataxia, dyskinesia, or hypoesthesia. Nor do they represent impairment of language understanding or recognition of objects or dementia. Instead, the patients present with deficits of imitating meaningful or meaningless gestures, purposeful use of objects, or dexterity. The term apraxia (Greek: inactivity) was coined by Heymann Steinthal to describe failures in the performance of purposeful actions and the incorrect use of objects by patients with aphasia (Steinthal 1871, 1881). The different forms of apraxia originate from lesions of different levels/structures of the motor system, reflecting its complexity. Apraxias are caused by deficits in motor programs generated in the frontal motor areas (executive apraxias, e.g., limb-kinetic apraxia), in the modality-specific higher sensorimotor control (unimodal apraxias, e.g., tactile apraxia, optic apraxia), or at the highest level of motor planning and motor conception (polymodal apraxias, i.e., ideomotor and ideational apraxias). Polymodal apraxias typically result from left hemisphere lesions and are therefore often, but not necessarily, observed in combination with aphasia.

Historically, most influential were the definitions of complex forms of apraxia: the ideatory and ideomotor apraxia syndromes as defined by Liepmann (1920). They are caused by lesions of the language dominant hemisphere, though their manifestation is bilateral (i.e., contra- as well as ipsilateral). In rare cases, with a lesion of the callosal fibers, a unilateral form of ideomotor apraxia in the extremities ipsilateral to the language dominant hemisphere can be observed. In those forms of apraxia as defined by Liepmann, the disturbance of execution of complex movements results either from incorrect action planning (ideational apraxia) or from the incorrect conversion of correct planning into correct performance of actions or action sequences (ideomotor apraxia). Thereby, two main components of action planning and execution can be distinguished: (1) an action concept system, containing knowledge of the tool use and of the basic mechanical constraints (damage leads to ideatory

apraxia) and (2) an action production system, with information about the motor programs and their conversion into learned movement patterns (damage leads to ideomotor apraxia) (Roy and Hall 1992). Liepmann (1920) also differentiated a third component, this of the “kinetic memory” of the “sensomotorium” in which overlearned movement patterns are stored and whose damage leads to an isolated limb-kinetic apraxia of the opposite hand. Traditionally, the investigations of patients with such complex forms of apraxia concentrated on disturbances of the three most important domains of action performance: imitation of meaningless gestures, performance of meaningful gestures on verbal command (pantomime), and the use of tools and objects. Interestingly, isolated deficits can be observed in all three domains, and these deficits can dissociate from each other. In Liepmann’s terminology, deficits of imitation of meaningless gestures and in pantomime are characteristic for ideomotor apraxia, and object use is typically deficient in ideatory apraxia. Since the expression of deficits in the three domains can vary among patients with apraxia and the borders between the ideomotor and ideatory apraxia are blurred, in the modern apraxia research, there is a strong tendency to use the term limb apraxia for complex apractic disturbances within the three domains (imitation, observation, and object use). Although in the light of the modern research, the Liepmann model cannot longer be regarded as valid, it has had a strong influence on the development of apraxia research. The terms ideomotor and ideatory apraxia are still widely used in the clinical practice.

In clinical examination, apraxia can be found quite often in patients with stroke. According to De Renzi (1989), apractic disorders can be found in dependence of the applied testing in 30–50 % of left brain damaged patients and in 2–9 % of right brain damaged patients. Aphasia (a disorder of language perception and production) and apraxia may often occur simultaneously, but their grades of severity do not correlate. Some studies could demonstrate a (double) dissociation of impairments in language functions and practice, which suggests that the neural organization

of these two functions is organized in at least, in part, structurally different networks. The natural history of apraxia is quite heterogeneous – of those patients who were apractic in the first week post onset of infarction, approximately half were still apractic after 3 months and remained apractic in about 20 % of cases (Basso et al. 1987; Kertesz and Ferro 1984). The different types of apraxia differentially affect the activities of daily living and hence show marked differences in the prognosis of recovery and the need of physiotherapeutic treatment.

With reference to the work of De Renzi (De Renzi and Luchelli 1988) and Goldenberg (e.g., Goldenberg 1996, 2006), the following modern classification of apraxias can be proposed:

- Executive Apraxias

The executive apraxias are characterized by deficits in the execution of complex movement components. Representative forms are the limb-kinetic apraxia and the speech apraxia. They are the consequence of the disturbed “premotor” functions of the caudal frontal lobe which is acting as a store and a processor of complex actions. Lesion-induced interruptions of the parieto-premotor information flow often play an important causal role.

- Limb-Kinetic Apraxia

The limb-kinetic (also innervation or melokinetic) apraxia manifests itself as the inability to accomplish finely coordinated and precise hand movements (Kleist 1911; Liepmann 1920). The higher the demand on finely tuned motor control, the more awkward is the movement execution. This syndrome is rarely diagnosed, mainly because the distinction from paresis resulting from a lesion of pyramidal system is difficult. There is also, as of yet, no standardized test for limb-kinetic apraxia. The characteristic clinical diagnostic features are awkwardness of arm and hand movements, disturbance of fine motor skills, dexterity, coordination of exploratory finger movements, writing and of the joint coordination, all that which is associated with preserved force production and individual finger movements.

Limb-kinetic apraxia results in the most cases from lesions of the premotor cortex and manifests itself contralaterally. It may also develop with basal ganglia diseases such as corticobasal degeneration or the Parkinson’s disease (Leiguarda and Marsden 2000).

Limb-kinetic apraxia is well accessible to physiotherapeutic measures, much better than many forms of paresis. The patients profit very well from intensive structural exercise.

- Speech Apraxia

In speech apraxia, the composition of articulatory movements to produce language sounds and words is disturbed. Patient’s speech seems weary; it is slow and disfigured by phonetic deviations. When speaking, the patients give the impression that they must consciously control their mouth movements, the coordination of the speech apparatus, and respiration.

The diagnosis of a speech apraxia is based on analysis of the linguistic utterances of the patient, particularly with missing symptoms of aphasia or dysarthria. Advanced planning of speech movements is disturbed and sounds are poorly coordinated. With speech apraxia, individual movements of the mouth can be accomplished with normal strength and speed, but they cannot be coordinated for fluent execution of speech.

Speech apraxia results most frequently from left frontal lesions, in or around the gyrus precentralis (parts of Broca’s area), and subcortical structures may also be affected.

Patients, who are moderately to heavily affected, should begin the therapy with the exercise of pronunciation and intonation of simple syllables. Performance of correct movements of the lips and the tongue might be helpful. Some patients may improve their articulation by rhythmic knocking or clapping. The exercise of pronunciation should be aligned to the natural speech rhythm in order to improve comprehension.

- Unimodal Apraxias

Unimodal apraxias are localized within one sensory system and manifest themselves predominantly on the contralateral side to the lesion. Typical representatives are the tactile

apraxia and the optical (visuomotor) apraxia (also optic ataxia).

– Tactile Apraxia

In tactile apraxia (Klein 1931), explorative finger movements are mainly affected with simultaneous absence of paresis or sensory deficits. The finger movements are uncoordinated and inadequate in relation to size and shape of objects to be explored (Binkofski et al. 2001). Typically, the intransitive (not object-related) and expressive movements such as gestures are well preserved. Tactile apraxia is often accompanied by the inability to recognize objects by tactile exploration, despite the well-preserved basic sensory and motor functions which is called astereognosia (Binkofski et al. 2001; Wernicke 1876). Tactile apraxia results typically from lesions of the contralateral superior parietal lobulus and/or the more anterior part of the intraparietal sulcus. If the caudal parts of the gyrus postcentralis are affected, accompanying disturbances of somatosensory qualities can occur. Since the disturbed handling of objects is the central failure in tactile apraxia and frequently a concomitant disturbance of the tactile object recognition is present, the patients are often significantly impaired in daily life (Delay 1935; Binkofski et al. 1999). In particularly severe cases, the hand can be useless, despite intact motor and sensory function. Dedicated intensive physiotherapeutic measures and learning of alternative strategies can provide good results.

– Optic Ataxia

In 1909, optic ataxia was first described by Balint (1909) as part of a broader visuoperceptive deficit. Optic ataxia is characterized by an inaccuracy when reaching for visually located objects. The terms visuomotor ataxia or optic apraxia are being used synonymously. The typical behavior of a patient with optic apraxia includes misreaching toward objects, in particular when the objects are not centrally fixated by the patient. In some patients, misreaching is present only in one arm but in both hemifields (hand effect), in others in both arms in the contralesional visual field (field effect). The most frequent deficit is present in the

contralesional arm and in the contralesional hemifield. Typically, the patients are capable of reaching toward their own body parts or toward objects, which are localized on the body surface. For the diagnostics of optic apraxia, goal-directed reaching should be examined with each arm and in both peripheral hemifields under simultaneous central fixation. In many studies regarding optic apraxia, lesions of the superior parietal lobulus were reported (Ratcliff and Davies-Jones 1972). Newer studies localize the critical lesion site within the parieto-occipital junction and the adjacent intraparietal sulcus (Karnath and Perenin, 2005). The most severely affected patients show misreaching also for centrally fixated objects. These rather rare cases are usually associated with larger or bilateral lesions. These patients have difficulties getting along in unusual environments. Patients with smaller and one-sided lesions are often mildly affected. If the optic apraxia is limited to the periphery of the visual field, compensatory strategies can be practiced, in which the patients first learn to turn their gaze to objects and then to reach for them under central fixation.

– Limb Apraxias

The execution of simple movement components is not affected in limb apraxias; the deficits of action execution depend rather on the context in which the motor action is implemented. An important feature of limb apraxia is that the disturbance of action execution manifests itself on both sides of the body (ipsi- and contralateral to the lesion). The disorder affects mechanisms of action conception which are operating on a hierarchically higher level than the purely contralateral action execution and sensorimotor control. Such apraxia can manifest itself both in the extremities and in the face, in the latter case it is called buccofacial apraxia. Up to 80 % of all aphasic patients have a buccofacial apraxia. Limb apraxia manifests itself in three domains of motor behavior: imitation of meaningless gestures, execution of meaningful gestures on verbal command, and use of tools and objects. Since each of them can vary in dependence of localization and lateralization of the lesion, Goldenberg is proposing their separate examination

(Goldenberg 2006). In everyday life, patients with lighter forms of limb apraxia are rather inconspicuous, their deficit is revealed predominantly in the experimental situation, mostly if they are requested to perform a pantomime of object use after verbal or visual presentation of the object. Whereas most errors occur during the pantomime of the object use, the patients show clearly less remarkable findings during the real use of objects. The impairment of object and tool use is a cardinal symptom of severe limb apraxia. Patients with this type of apraxia are severely impaired in their daily life. Limb apraxia is typically associated with lesions of the language dominant hemisphere. The imitation of simple and complex movements can be affected after lesions of the left frontal and parietal cortex, this deficit can be seen more frequently after lesions of the parietal cortex (De Renzi et al. 1983). Many patients with lesions of the left parietal lobe seem to have difficulties to execute and to analyze movements, which refer to their own body schema (Halsband et al. 2001). The lateralization of the deficiency in imitation of meaningless movements is specific for the body part: Left brain lesions affect imitation of hand and foot postures more than of finger postures. Right brain lesions do not have an influence on hand and only slight one on foot postures, but may cause marked deficits in imitation of finger postures (Goldenberg 1996). Within the left hemisphere, lesions of the lower parietal lobe (supramarginal gyrus) are particularly important. Also, deficits of pantomime of transitive (object-related) movements can be seen predominantly after left hemispheric lesions. Conversely, deficits in the pantomime of intransitive (not object-related) movements seem to be distributed over both hemispheres (Haaland and Flaherty 1984). Patients with right hemisphere lesions do not have problems with the pantomime of meaningful gestures. Patients with deficits in object use have usually large lesions, which include the temporoparietal region in the language dominant hemisphere (Goldenberg and Hagmann 1998). Patients with left hemispheric lesions have difficulties to select objects fitting to such movements, which were shown to them as

pantomime of the object use (Vaina et al. 1995). They have also difficulties with pantomime of object-associated movements (Goldenberg and Hagmann 1998; Goodglass and Kaplan 1963) or with the selection of objects, which are to serve the same purpose (Rumiati et al. 2001). The integrity of the left hemisphere is crucial for establishing association of tools with purpose, recipient, and action, and the inference of function from structure. Many patients with limb apraxia need significantly more assistance than non apractic patients (Sundet et al. 1988). The deficit of imitation can also have a negative influence on motor learning in physical and occupational therapy. The inability to express the meaning of objects or actions by gestures reduces the ability of patients with severe aphasia to compensate their language deficits by nonverbal communication (Borod et al. 1989). Therefore, “gesture training” can provide positive results. A clear reduction of faulty actions and patients’ need for assistance could be found only after the direct training, in which concrete ADLs were learned. On the other hand, the patients could not concretely use the new insights about the object use they have gained from the exploration training. Apparently, only those patients who practice on a regular basis can keep the level of improvement high (Goldenberg and Hagmann 1998), patients who stop practicing deteriorate. The therapeutic aims for patients with ideational apraxia should be strongly orientated toward the domestic environment and on the desires of the patients and their family members.

Description

The architecture of Islam covers a very wide chronological and geographic expanse. The birth of this architectural tradition dates back to the first half of the seventh century, almost 1,400 years ago. Geographically, it extends across an expanse that includes considerable areas in Asia, Africa, and Europe, covering the Near East – where Islam was born, in the Arabian Peninsula – and extending into areas as distant and diverse as Spain, North Africa, sub-Saharan Africa, East and South Europe, Central Asia, South Asia, and East Asia.

The study of the architecture of Islam gradually emerged as an academic field of inquiry over the past two centuries or so and has been

primarily formed in the West. One of the difficulties associated with attempting to understand the field has been the stubborn preoccupation with bringing this diverse chronological and geographic architectural production under the umbrella of one unifying category, that of “Islamic architecture.” This has begun to change, particularly over the past two decades, as the field has achieved higher levels of specialization as a result of various factors including its maturing age and also because an increasing number of institutions and scholars have become involved in the field and a substantial number of studies have been published on it. Still, the legacy of a unifying single category remains very strong and present, particularly among those not specialized in the field, including architects as well as architectural historians and critics.

In attempting to understand the architecture of Islam as a field on inquiry, a point of departure would be to present it within the context of three simple and basic, but interconnected, systems of categorization: chronological, geographic, and typological.

There are a number of manners through which one may present the chronological evolution of the architecture of Islam. What follows is only one of a number of possible scenarios. The birth of the architecture of Islam symbolically may be traced to the construction by the Prophet Muhammad of his house and mosque in Medina in 622, which is the year of the *Hijra*, or the Prophet’s pilgrimage from Mecca to Medina, the founding of the first Islamic state, and the beginning of the Islamic calendar. The building activity that took place under the Prophet and his four successors (known as the Orthodox Caliphs) remained rather modest in its symbolic aspirations and made no pretenses at achieving any level of monumentality or grandeur. It was under the first Muslim imperial dynasty, that of the Umayyads (661–750), that a deliberate will for achieving such monumentality and grandeur in architecture came into being, as evident in their main constructions of the Dome of the Rock and the Aqsa Mosque in Jerusalem, and the Umayyad Mosque in Damascus, all dating to the late seventh and early eighth centuries.

The Abbasid dynasty (750–1258), which violently overthrew the Umayyads, continued this imperial tradition of architecture. Their earliest most prominent building effort was the founding of their capital, the city of Baghdad, in 762, which was designed as a circular walled enclosure with a diameter of about 2 km but quickly grew beyond its pure geometric confines. The Umayyad and the early Abbasid periods generally are considered to belong to the “early” Islamic architectural tradition. This was a formative period in which new architectural vocabularies were established through a process involving a considerable borrowing and transformation of prototypes from the architectural traditions of the two empires that ruled much of the earliest regions to become part of the Islamic world. The first empire is that of the Sasanians, which ruled Iran and Iraq and which the Muslims eliminated, and the second is that of the Byzantines, which ruled in Anatolia, Syria, and Egypt and which the Muslims greatly weakened. The Umayyads initially expressed a stronger reliance on Byzantine rather than Sasanian prototypes, but as the political and economic weight of the Muslim empire gradually shifted eastward, Sasanian influences increased considerably by the late Umayyad period to become overwhelmingly dominant by the advent of the Abbasids.

This formative early period of about two centuries is followed by what art and architectural historian Oleg Grabar identified as a “classical” period of Islamic architecture and this usually is marked by the construction of the expansive Abbasid royal suburb of Samarra outside Baghdad in 836. With the advent of this classical period, architectural references became primarily internal and no longer heavily dependent on outside prototypes. During that same period, the Umayyads, who managed to survive and maintain their rule at the western edge of their far-flung Muslim empire in the Iberian Peninsula (or al-Andalus in Arabic) until 1031, also concurrently developed their own unique, independent, and mature architectural vocabularies.

The Abbasid dynasty began to show serious signs of political weakening by the tenth century,

bringing about a period of extensive fragmentation, with a series of smaller and often warring, though, in many cases, culturally vibrant independent states coming into being in various parts of the Islamic world. With this fragmentation, however, also came a high level of diversity and richness of architectural production. The Saljuq dynasty and its vassals did manage to achieve some consolidation of authority in the central Islamic lands beginning in the late eleventh century, with much of its weight being located in Iran and Central Asia. They were among the earlier of a series of rulers of Turkic origins that eventually ruled much of the Islamic world. Another wave of territorial consolidation, though a brief one, came with the devastating Mongol invasion during the thirteenth century, which extended across Asia and brought vast areas under Mongol rule including Baghdad in 1258, which, in spite of the political weakening of the Abbasid dynasty, had managed to remain a metropolis of tremendous symbolic and cultural importance.

The Mongols were followed by a number of powerful dynasties. These included the Ilkhanids, the successors of the Mongol rulers who had converted to Islam, the Mamluks, who ruled Western Asia and the Nile Valley from the middle of the thirteenth century to the early sixteenth, and the Timurids, the dynasty founded by Timur in the late fourteenth century and that brought much of Central Asia under its control. Each established its own unique and monumental architectural tradition. Samarkand and Cairo particularly provided magnificent urban and architectural expressions of the glories of the Timurid and Mamluk empires.

The next phase is the founding of what historian Marshall Hodgson termed the “gunpowder empires,” which coincided with the age of gunpowder and the use of firearms. These great empires are those of the Mughals in India, the Safavids in Iran and Central Asia, and the Ottomans in Turkey as well as Eastern Europe, Western Asia, and North Africa. These empires, which reached their zenith during the sixteenth and seventeenth centuries, were among the most powerful in the world, ruled much of the Islamic world, and provided a consolidation of authority

as well as an expansion of territories under Muslim rule not seen for centuries. Their architecture provided a major and conscious expression of their glory, as can be seen in representative well-known monuments such as the Taj Mahal in Agra (1632–1653), the Royal Mosque of Isfahan (1611–1638), and the Selimiye in Edirne (1568–1574). The latter monument is considered the masterpiece of the Ottoman architect Sinan, the most celebrated architect of the Islamic world's long and varied architectural legacy, and its most prolific. The weakening of those empires during the course of the eighteenth century marked the initiation of the modern era, which was accompanied by growing Western influence, often expressed through direct colonialism. With that, the architectural production of the Islamic world enters a new period, but this falls beyond the scope of this entry.

Geographically, the Islamic world may be divided into a series of regions defined by various factors including natural borders as well as linguistic, sectarian, and overall cultural bonds, with each region developing rather unique architecture traditions. While the natural borders are fixed, the cultural ones are very elastic, resulting in a frequent shifting of borders defining those regions and strongly affecting the nature of relationships between them. Still, a certain level of continuity marks this regional division of the Islamic world throughout Islamic history. Moving from west to east, the Iberian Peninsula, or al-Andalus, emerged as a very important region of the Islamic world after it became a separate principality under the Umayyads in the mid-eight century and until the Iberian Peninsula began to fall to advancing Christian European forces from the north in the early thirteenth century, a process that was completed with the fall of Granada in 1492. In addition to al-Andalus, the other Arabic-speaking regions of the Islamic world consist of North Africa, Egypt and the Nile Valley, the Fertile Crescent (Greater Syria and Iraq), and the Arabian Peninsula, with each expressing a rather separate architectural character. The architecture of North Africa greatly interacted with that of al-Andalus, while the latter was under Muslim rule. The

architecture of Egypt generally expressed a clear independent character and often had a strong influence on the architecture of Greater Syria. This influence became increasingly strong after the Fatimid dynasty, which was established in North Africa in 909, advanced into Egypt in 969, reaching Greater Syria soon after that. While Greater Syria is the birth place of the Islamic world's first imperial tradition, that of the Umayyads, its architecture with time became more integrated with, and often subjected to, the architectural traditions of the main regional powers, including the Abbasids, Fatimids, Ayyubids, Mamluks, and the Ottomans. The same applies to the architecture of Iraq, which played a crucial and central role in the development of the Umayyad and Abbasid architectural traditions. Although Iraq generally managed to maintain a level of cultural autonomy until the fall of Baghdad to the Mongols, this autonomy later on succumbed to the influences of larger empires such as those of the Safavids and the Ottomans.

Turkey of course is a most significant central region of the Islamic world and, beginning with the growth of the Ottoman Empire in the second half of the fifteenth century, became the center of architectural influence that extended into the various areas under Ottoman control, including East Europe, North Africa, and West Asia. No less important than Turkey is Iran, which played a most crucial role in the development of Islamic civilization since the early days of Islam although its widespread cultural influence was somewhat curtailed under the Safavids, when it became the main center of Shiite Islam while much of the other parts of the Islamic world were ruled by Sunni dynasties. In fact, it is Iran, Turkey, and the eastern Arabic-speaking lands (extending from Iraq in the east to Egypt in the west) that form what may be referred to as the "central" regions of the Islamic world, and it is there where a good part of the Islamic world's political and cultural developments originated.

This still does not minimize the importance of regions falling outside this "central" core, most importantly Central Asia, or what until recently were the former Central Asian republics of the Soviet Union and also Afghanistan. A number of

very important dynasties such as the Timurids were based in Central Asia, and significant urban centers of Islamic civilization such as Samarqand, Bukhara, Tashkent, Nishapur, Merv, and Herat are located in that region. The Indian subcontinent of course forms an integral part of the Islamic world although its relation to the Islamic world is very much complicated by the fact that in spite of its enormous Muslim population and that it was ruled by various Muslim dynasties for centuries, most notably the Mughals, the majority of its population remained Hindu.

To the east are the regions of East Asia, and in fact, Indonesia is today's largest Muslim country. The Islamic architectural traditions of East Asia, however, are more closely affiliated with preexisting local traditions than with those of other regions of the Islamic world. Interestingly enough, even though one associates Islam with its central regions, the majority of the world's Muslims in fact reside east of these central regions, in the Indian subcontinent and Eastern Asia (primarily Pakistan, Bangladesh, India, and Indonesia). And of course, various parts of sub-Saharan Africa such as present-day Mali and the Niger produced their own unique and rich architectural traditions, even though their role in the overall political and cultural developments affecting the Islamic world remained peripheral.

One manner in which the architecture of these different regions may be differentiated is through the primary building material used in them, particularly stone and brick. One cannot and should not draw clear-cut lines of division. Still, stone generally is prevalent in the architecture of regions such as Turkey, Greater Syria, Egypt, and India, while brick is the common construction material in regions such as Iraq, Iran, and Central Asia. These two materials were used both for structural purposes and for sheathing surfaces. Another important surface-sheathing material is glazed tiles, of which impressive examples are found in Turkey, Iran, and North Africa. Mosaics were particularly common for covering surfaces in the early Islamic architecture of Syria and al-Andalus, and stucco was widespread in various parts of the Islamic world and at different periods.

Wood, while not common as a structural material, was widely used for specific elements such as wall and ceiling panels, as well as for screens and balconies.

From a typological point of view, a certain level of confusion has always evolved from the use of the term "Islamic architecture" as it gives a religious overtone to that architectural production even though it fully covers both religious and secular buildings. Of course, the most prominent building type of the architecture of Islam remains a religious building: the mosque. Every city was to have a main congregational mosque where the Friday prayers led by the ruler would take place, with the mosque and house of the Prophet in Medina being the first example. Many cities, however, early on became too large to be served by a single congregational mosque and had to be served by more than one. In addition, there are the smaller mosques that serve the various districts or neighborhoods of the city.

Other buildings with strong religious connotations include the mausoleum, the earliest surviving example of which is the octagonal al-Qubba al-Sulaybiyya in Samarra from the second half of the ninth century. In it, three Abbasid rulers were buried. By the middle of the twelfth century, mausoleums were often combined with mosques to form a unified architectural complex. Out of the mausoleum also developed the important building type of the shrine, or mashhad, which commemorated an important religious person. In this context, mashhads commemorating religious events existed since the early days of Islam, with two prime examples being the Ka'ba in Mecca, which is associated with events from the life of Abraham and marks the direction which Muslims face when praying, and the Dome of the Rock in Jerusalem, which is associated with Prophet Muhammad's night journey to heaven.

Another important structure with religious connotations is the madrasa, or the institution where religious scholars were educated. The earliest were built by the Saljuqs during the eleventh century, with the earliest surviving examples dating to the first half of the twelfth century. These too often were combined with the mosque or – by the twelfth century – the mausoleum (usually of

the patron), and it is not unusual to have complexes containing all three. Architecturally, some of the most magnificent surviving examples of these combined complexes are found in Mamluk Egypt, as with the mid-fourteenth-century complex of Sultan Hasan in Cairo. There also are other building types with religious connotations such as the Ribat, which essentially is a fortified enclosure for religious warriors, or the Khanqah, which is a hostel for sufis.

There of course is an abundance of public buildings of a secular nature in the Islamic world. Some were intended as philanthropic structures that provide services to the public, such as the *sabil*, or public water fountain. There also are other constructions connected to the theme of water, such as aqueducts and reservoirs, all incorporating sophisticated methods for collecting, conveying, and storing water. A unique water-related structure is the mid-ninth-century Abbasid-era Nilometer in Cairo, which consisted of a marked column located in the middle of well-like space that was connected to the Nile by tunnels. The Nilometer measured the level of the waters of the Nile for the purposes of determining taxes for a given year.

Another common building type is the public hospital, known as the maristan or bimaristan. A well-known and relatively early example is the mid-twelfth-century bimaristan of Nur al-Din in Damascus, which the Zangid ruler Nur al-Din built (the Zangids were one of a number of dynasties founded by governors appointed by the Saljuqs). Public baths, or hammams, were also significant urban public structures. Although the earliest surviving baths are private ones found in the palatial residences that the Umayyads built in the Syrian desert, they evolved into public structures and an integral component of cities in the Middle East and North Africa.

There also are numerous commercial structures and complexes that were developed in the Islamic world, which is not at all surprising considering the central role that trade played in its economic life. These include the *suq* (*souk*), or market, the khan, and caravanserai, as well as the wakala, the urban caravanserai that contained storage areas on the ground floor with accommodations units for traveling merchants above.

And there is no shortage of princely residences although these have not survived as well as religious buildings since succeeding dynasties were not particularly concerned with preserving the symbols of power of those preceding them, and in some cases deliberately destroyed them. What does survive, however, is spectacular, as evident in two of the best-known palaces of the Islamic world, the Alhambra in Granada and the Topkapi in Istanbul, both of which evolved over centuries, with the Alhambra coming into being in the thirteenth century and the Topkapi in the fifteenth. In addition, there is that most interesting and still not fully understood group of early palaces constructed by the Umayyads during the seventh and early eighth century in Syria, mainly along the edges of the Syrian desert, and which provide the first surviving examples of Muslim palaces.

Numerous examples survive of military architecture. Some had clear religious connotations as with the ribats. Although the ribats were located outside cities, many military structures, particularly the citadel, occupied commanding locations in cities, often along city walls. One of the most magnificent is the Citadel of Aleppo, which began to take its present shape during the Crusader period particularly in the second half of the twelfth century, under the rule of the Zangids, but evolved considerably over the next few centuries. The site, however, was used for military purposes as early as the third millennium BC. In this context, it is important to keep in mind that numerous important monuments in the Islamic world were built on the remains of pre-Islamic structures.

The various building types of the Islamic world of course often came together in many complexes. The Citadel of Aleppo, for example, not only housed military facilities but also had residential as well as religious ones, in addition to water collection, storage, and distribution facilities.

Finally, one cannot ignore the urban scale. Islam was very much an urban religion connected to urban centers, and the architecture of the Muslim world very much is an urban architecture. One expression of this emphasis

on urbanism is how Muslim rulers established numerous new cities in different locations and in different periods. Cities were established since the earliest days of Islam, as is the case with Basra and Kufa in Iraq, both of which initially were founded during the rule of the Orthodox Caliphs as garrisons for Muslim armies but quickly grew to become full-fledged cities. During their heyday, many of the cities of the Islamic world, such as Baghdad, Cairo, Cordoba, Isfahan, and Istanbul, were major cosmopolitan metropolises and great international centers of commerce, culture, and learning.

Clearly, there is considerable diversity in the architecture of the Islamic world. However, there also are certain visual elements that linked the architectural production of its various regions. The dome is common in many parts of that world and so are the minaret and the iwan (a vaulted space enclosed on three sides and entirely open on the fourth, often onto a courtyard). Calligraphy was a common feature for articulating buildings, providing documentary information on the buildings as well as presenting their symbolic significance. Certain decorative features, such as the muqarnas (also known as stalactite or honeycomb vaults) as well repetitive floral and geometric decorative patterns (known as the arabesque), can be found in regions as diverse as the Indian subcontinent and Spain. Still, it should be noted that if one examines the architecture of the geographic “edges” of the Islamic world, such as East Asia or sub-Saharan Africa, it is noticed that these various elements generally are not incorporated in their unique and impressive architectural traditions.

[Calculation](#); [Reckoning](#)

Description

Arabic arithmetic exhibits two interconnected currents, the practical and the scientific. Before the ninth century CE practical arithmetic was traditionally communicated orally by trade groups, with emphasis on calculation and problem solving. Here the concept of “number” is any positive quantity which arises in calculation, including fractions and irrational roots.

Three systems of practical calculation were taught in medieval Islam: finger reckoning, Hindī numerals, and the base 60 system of the astronomers. Merchants preferred finger reckoning. In this system calculation is done mentally utilizing clever shortcuts, and intermediate results from 1 to 9,999 are “stored” by positioning the fingers in particular ways. Different problem-solving methods were associated with finger reckoning, including double false position and algebra. Al-Khwārizmī’s lost *Book of Adding and Subtracting*, written in the early ninth century, was probably devoted to this method. If so, it is the earliest known *written* text on the subject. One famous book, which inspired many later works, is al-Karajī’s *The Sufficient [Book] of Arithmetic*, composed in the early eleventh century. The author covers practical mensuration in addition to arithmetic.

Our “Arabic” numerals 1, 2, 3, etc., were called by the Muslims “Hindī” numerals, because they acquired the system from India. The numerals were already in use in the Middle East by the seventh century CE, and the earliest known

Arabic text is al-Khwārizmī’s *Book on Hindī Reckoning* (early ninth century), which survives only in Latin translation. Originally, the algorithms for calculating in this system were devised for use on a dust board where erasing is easy. In the mid-tenth century al-Uqlīdisī presented new algorithms for use with pen and paper, partly to dissociate the method from the work of astrologers who calculated with the dust board. One Arabic contribution is decimal fractions, described for the first time by al-Uqlīdisī (tenth century) and later exploited by mathematicians such as Jamshīd al-Kāshī (early fifteenth century).

Since Babylonian times astronomical calculations were performed and recorded in base 60. In Greek texts the letters of the alphabet designate the numbers 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 20, 30, etc. In this way 42 was written “MB,” where “M” represents 40 and “B” is 2. To write a hexadecimal number like “2; 13, 42, 0, 45” $\left(2 + 13\frac{1}{60} + 42\frac{1}{60^2} + 0\frac{1}{60^3} + 45\frac{1}{60^4}\right)$, a Greek text will have “B ΙΓ MB ο ME,” where a special symbol fills the empty place, and the order of magnitude is (usually) not indicated. Arabic astronomers learned the hexadecimal system from Ptolemy’s *Almagest*, and their *jummāl* system replaces the Greek letters with Arabic letters (Al-Uqlīdisī 1978).

Trigonometric tables and algorithms for calculating roots were composed for both the Hindī and the *Jummāl* systems. To give two late examples, Berggren describes al-Kāshī’s extraction of the fifth root of 44,240,899,506,197 in Hindī numerals and his calculation of 2π in hexadecimal, via trigonometric identities and the square root algorithm, to an accuracy equivalent to 16 decimal places (Berggren 1986, pp 20, 53ff).

In contrast to practical calculation, scientific Arabic arithmetic is an extension of Greek number theory, originating in the arithmetical books of Euclid’s *Elements* and in Nicomachus’ *Arithmetica*. Books typically cover number sequences, series summation, polygonal numbers, and perfect/amicable numbers. Following the lead of the Greeks, only positive integers were considered to be numbers in scientific texts.

Arabic mathematicians made particular progress in aliquot parts. Two numbers are *amicable* if each is the sum of the proper divisors of the other. The pair 220, 284 was known to Iamblichus in late antiquity. Thābit ibn Qurra (ninth century) derived and proved a remarkable rule for generating amicable numbers: if three prime numbers p_1 , p_2 , and p_3 take the form $p_1 = 2^{n+1} - 1 + 2^n$, $p_2 = 2^{n+1} - 1 - 2^{n-1}$, and $p_3 = 2^{n+1}(2^{n+1} + 2^{n-2}) - 1$, then the two numbers $2^n p_1 p_2$ and $2^n p_3$ are amicable. For $n = 4$ this generates the pair 17,296, 18,416, probably found by Thābit, and reported later by al-Fārisī (d. ca. 1320) (Hogendijk 1985). Later authors, beginning with al-Baghdādī (ca. 1000), introduced “balancing numbers.” Two numbers satisfy this condition if their proper divisors sum to the same number. The pair 39, 55 is frequently mentioned.

Many books give formulas for series summation. Al-Qābisī’s tenth century treatise on this topic includes both old and new results. One interesting example not known from any Greek source, and later proven by Ibn al-Haytham, is:

$$1^4 + 2^4 + 3^4 + \cdots + n^4 \\ = \left(n^2 + \frac{n}{2}\right)(n+1) \left(\left(\frac{n}{5} + \frac{1}{5}\right)n - \frac{1}{15}\right).$$

This and other results are expressed all in words, with no symbolism (Sesiano 1987).

Many practical texts give definitions and examples of perfect, amicable, and balancing numbers, as well as formulas for series summation.

Arithmetical Problem Solving

The different problem-solving methods illustrated in arithmetic textbooks including single false position, working backward, analysis (*al-tahlīl*), double false position, and algebra. Many books employ two or more methods for the same problem, like this one from an arithmetic text of al-Fārisī (early fourteenth century): “a quantity: you doubled it and you took away from it a dirham. Then you doubled the outcome

and you took away from it a dirham, leaving ten dirhams.” (We can convert this to the modern algebraic equation $2(2x - 1) - 1 = 10$.) Al-Fārisī solves it three ways, by algebra, analysis, and double false position.

For reasons of space I will describe only double false position here (algebra is covered in the entry “Algebra in Islam”). In this method two guesses are made for the value of the unknown, and the solution is found from the guesses and their errors. For this reason it was called the method of “the two errors” (*al-khaṭa’ayn*) in Arabic. Al-Fārisī’s solution to the problem posed above is:

And by the two errors, you suppose the sought-after [quantity] is ten. So its double less one is 19, and its double less one is 37. The difference between it and the known 10 is an added 27.

Then you suppose it is six, and its double less one is 11, and its double less one is 21. The difference between it and 10 is 11, also added.

So multiply the first guess, 10, by the second error, 11: you get 110. And multiply the second guess, I mean 6, by the first error, I mean 27, so it gives 162. And since the two errors are added, take their sum: it yields 52. And divide it by the difference between the two errors, I mean 16. It results in three and a quarter, which is the desired [quantity].

The method of double false position was proven to be correct by geometry by Qusṭā ibn Lūqā in the ninth century, but it seems to have attracted no further scientific interest.

Arrow of Time

Russell Stannard
Department of Physics and Astronomy,
Open University, Milton Keynes, UK

This refers to the fact that, given a filmed sequence of events, it is more often than not possible to tell which way round the film should be shown. For example, it is much more likely that a chimney will collapse into a pile of rubble, rather than a pile of rubble will spontaneously assemble itself into a chimney. There is a tendency toward increasing disorder with time. It is closely associated with the operation of the second law of thermodynamics.

Main Text

Description

Studio Art has historically been understood as a discipline involved with the practice of making paintings, drawings, prints, and sculptures for the purpose of aesthetic contemplation. Since the late nineteenth century, this definition has been continually expanded to include a variety of media and processes, including (but not limited to) photography, collage, computer imagery, conceptual art, performance art, earthworks, video, soundscapes, and installation art. While many artists continue to use traditional media such as oil paint, watercolors, engraving, lithography, stone carving, and bronze casting, others use the ordinary materials of everyday life to make found-object or welded-steel sculptures, mechanical objects controlled by computers, or all-encompassing environments which the audience enters rather than viewing from a safe distance.

At the same time that the materials and processes of Studio Art were expanding, the definition of Studio Art has been continually contested by artists, museums, galleries, schools, and theoretical-critical institutions. Throughout the twentieth century, a variety of movements and styles emerged, including futurism, constructivism, dada, formalism, expressionism, minimalism, photo-realism, pop art, and many others. Many of these movements and styles were accompanied by

manifestos and theoretical constructs that explicitly rejected notions of aestheticism and defined Studio Art in political, social justice, or spiritual terms.

The definition of Studio Art has also been contested by those whose work was not traditionally recognized as within the discipline. In the last few decades, practitioners of crafts such as weaving, quilting, pottery, glassblowing, and woodworking have sought, with some success, to have their work recognized as Studio Art. The discipline of Studio Art has also begun to recognize the works of artists not trained within the academy, naming it variously as Visionary, Outsider, or Primitive Art.

The most recent movement in Studio Art has been termed “Postmodernism.” It is characterized by the appropriation of elements from past styles and movements, references to contemporary pop culture, an ironic tone, and a blurring of the boundaries between high and low art.

Today, Studio Art may best be understood as the practice of making objects and experiences that externalize a particular way of viewing the world, express their cultural context, and reflect that context in a way that may affect the collective conscience of that culture (Danto 1981).

Self-Identification

Science

The discipline of Studio Art is not a science, although some artists use the language of science, or attempt to promote their art as science, often collaborating with scientists in experiments that involve light and/or sound. However, even when artists use scientific ideas and processes, or speak in scientific terms, they do so for purposes that are different from those of scientists. The purpose of Studio Art is, broadly speaking, the exploration and communication of ideas, feelings, or experiences through visual, tactile, spatial, and other media. While Studio Art is a way of knowing (*scientia*), it is not a science as that term has come to be understood.

Characteristics

Studio Art is distinctive in that it uses materials and processes, rather than words, to explore and communicate its discoveries and insights.

Relevance to Science and Religion

While it is virtually impossible to speak of the interests of Studio Art as a whole, there are many Studio Artists who are interested in science, religion, and the intersection between them, as subject matter for artworks.

Sources of Authority

The sources of authority for the discipline of Studio Art include the artworks and artifacts of earlier periods and cultures; the writings of artists about their own processes, materials, and intentions; and the ongoing tradition of critical-historical reflection on these artworks and artifacts. In the modern and postmodern era, specific authorities include curators at major museums of art, such as the Metropolitan Museum of Art, the Museum of Modern Art, and the Guggenheim in New York City; the Art Institute of Chicago; The British Museum, the Tate, and the Tate Modern in London; or the Louvre, the Centre Pompidou, and Musée d’Orsay in Paris; art critics, historians, or philosophers, such as Clement Greenberg, Harold Rosenberg, Lucy Lippard, or, more recently, Arthur Danto and James Elkins; influential art dealers, galleries, and collectors; and the artists, themselves. Publications generally recognized as authoritative include *Art Journal*, the organ of the College Art Association; *ArtNews*, a New York-based journal which is widely read throughout the world; *ArtWeek*, which offers thoughtful critiques and articles from the US West Coast; and *Art Monthly*, a well-regarded British journal on contemporary art. These sources become authoritative to the extent that they affect the subsequent discourse about and practice of Studio Art.

Ethical Principles

Since individual artists work from an enormous variety of cultural, religious, and personal viewpoints, it is virtually impossible to say that the discipline as a whole is guided by specific ethical principles.

There is a strong strand within artistic thought that values the traditions of the past and seeks to maintain continuity with those traditions. Concepts such as beauty, transcendence, and mystery

are often invoked, especially when the artworks are intended for religious or spiritual communities. The ethical principles guiding such artists often include reverence for God and/or nation, and respect for individuals as well as for social structures.

An equally strong tradition views art as an essentially subversive activity, whose task is to critique society. Such critique may take the form of apparently destructive acts, or images intended to shock the viewer, or experiences that are meant to distort perceptions. For those who see art as subversive, such destruction, shock, or distortion is understood as the necessary (and therefore ethical) means toward the desired end of a better world. Often, but not always, the implicit or explicit ethical principles of such subversion include world peace, ending poverty, promoting ecological harmony, and similar ideas.

A third view is that art stands outside of ethical considerations, existing only for its own sake as aesthetic experience. For those who hold this view, any attempt to force art to address ethical issues is to violate the integrity of art as such.

Key Values

Integrity, authenticity, creativity, innovation, cultural awareness, craftsmanship, design

Conceptualization

The discipline of Studio art, as a whole, does not directly address questions of Nature/World, Human Being, Life and Death, Reality, Knowledge, Truth, Perception, Time, Consciousness, Rationality, or Mystery, and does not have a consensus on how to conceptualize them. Many in the discipline simply accept the everyday definitions of the terms, without attributing any special meaning to them with regard to their work or that of artists generally. Others maintain that questioning any definition of any one or all of these ideas is central to the practice of Studio Art, making such questioning the implicit (and often explicit) subject matter of their work. Still others may make some specific definition, or set of definitions, of these terms foundational to their practice.

Relevant Themes

One of the issues that for some time has been marginal, but is currently becoming central to the discipline is the relationship between art and religious faith. There is a growing interest among studio artists in the question of how to make art that is considered excellent in the contemporary art world while maintaining the integrity of religious belief and practice. In the western world, the Reformation and the Enlightenment drove a wedge between Art and Religion, causing each field to be somewhat suspicious of the aims and practices of the other. Toward the end of the twentieth century, some artists and thinkers, on the one hand, and some religious bodies, on the other, have come to question this mutual antagonism, as they recall that Art and Religion have generally been allies throughout most of history. This issue is critical as artists of faith seek ways to communicate their religious understandings in works that are consistent with contemporary ideas and values in the art world generally; and as churches, synagogues, and other religious institutions seek ways to embody their insights and doctrines in symbols and images that are relevant to twenty-first century worshippers.

Artificial Immune Systems

Dipankar Dasgupta

Computer Science Department, The University of Memphis, Memphis, TN, USA

Related Terms

[Immunological computation](#)

Description

The field of artificial immune systems (also called immunological computation, or just AIS) is an area of study devoted to the development of computational models and techniques based on the principles of the biological immune system (BIS). Specifically, it is an emerging area that explores and employs different immunological mechanisms to solve computational problems.

The BIS is a complex, adaptive, highly distributive learning system endowed with several alternative and complementary mechanisms for defense against pathogenic organisms. The immune system learns, through adaptation, to distinguish between dangerous foreign antigens and the body's own cells or molecules. Clearly, nature has been very effective in creating organisms that are capable of protecting themselves against a wide variety of pathogens, such as bacteria, fungi, and parasites.

The powerful information-processing capabilities of the immune system, such as feature

extraction, pattern recognition, learning, memory, and its distributive nature, provide rich metaphors for its artificial counterpart. Since 1985, there has been an increased research interest in immunity-based techniques and their applications. Some of these models, however, are intended to describe the processes that occur in the BIS to have a better understanding of the dynamic behavior of immunological processes and simulate BIS's dynamic behavior in the presence of antigens/pathogens. In contrast, immune-inspired models have been developed in an attempt to solve complex real-world problems, such as anomaly detection, pattern recognition, data analysis (clustering), optimization, and computer security.

Theoretical models of immune processes have attempted to explain adaptive immune response. For instance, the immune system's ability to "remember" its encounters with antigens to achieve a faster response when the similar antigen is confronted at a later time has been modeled by immune networks and danger theory models.

In order to formulate theoretical and computational models, it has been necessary to develop general abstractions of some immune elements and processes. Accordingly, some standard procedures, representations, and matching rules have been adopted in most immunological models.

Some representative immunity-based algorithms include the following:

- T-cell algorithms, which include negative selection, one of the earliest immune algorithms, are based on the negative selection (NS) process that occurs in the thymus.
- B-cell algorithms, which are mainly based on immune network theory and clonal selection principles.
- Danger theory approach, based on danger Theory introduced by Matzinger (1994), which states that the immune system is activated on receipt of molecular signals, which indicate damage (or stress) to the body rather than by pattern matching of "nonself" versus "self."
- Dendritic cell algorithms, which intend to capture the way dendritic cells serve to communicate innate and adaptive immune systems.

In addition, a significant amount of work has been done in combining some of these methods with other computational intelligence approaches, such as neural networks, evolutionary algorithms, fuzzy logic and swarm algorithms.

During the last two decades, immunological computation (IC) techniques (or artificial immune systems) are increasingly used as problem solvers in a wide range of domains, such as optimization, classification, clustering, anomaly detection, machine learning, adaptive control, associative memories, etc.

IC techniques have also been used in real-world applications, such as computer security, fraud detection, robotics, fault detection, data mining, text mining, image and pattern recognition, bioinformatics, games, and scheduling.

Self-identification

Science

The field of artificial immune systems is not a science by itself. It may be considered as a scientific and technological discipline, since it involves theoretical and applied aspects of several sciences and technologies – mainly biology, chemistry, mathematics, statistics, medicine, and computer science.

AIS have been considered mainly as a subarea of computational intelligence, along with the main representatives, namely, neural networks, fuzzy systems and evolutionary algorithms, and swarm intelligence.

Characteristics

Although artificial immune systems field uses a general biological system and processes as an inspiration, just as in other bio-inspired areas, such as neural networks (after biological neural networks) and evolutionary systems (after evolution of biological systems), AIS is distinctive among other specialties of Computational Intelligence and Bio-inspired computing by having immune mechanisms as the focal point of study. However, it is important to note that models used

to study other biological systems have also been used in the AIS.

Relevance to Science and Religion

The field of AISs is involved in studying a particular biological system, the immune system, and those natural processes related to it, and to model the understanding of its elements and processes from a scientific point of view and also on developing technological applications using metaphors of the natural system. Although it is believed that, in some cases, some metaphysical aspects may influence the biological immune system's behavior, such as psychosomatic diseases, no work has been done on trying to understand and model any other than biological and chemical aspects of the biological immune system.

As a scientific/technological discipline artificial immune system is relevant to the scholarly area "Science and Religion" to some extent. By its nature, artificial immune system is related to science. Since this discipline deals with many evolutionary processes, so has it also a concern to the interaction of science and religion which is described by the "conflict thesis" (http://en.wikipedia.org/wiki/Conflict_thesis). Although this thesis is rejected in the present-day context, still it indicates an elemental relevancy between a scientific discipline and religion. Artificial immune system not only studies those evolutionary processes, but it strengthens the practical aspect of those concepts by applying them on real-life problems. Apart from this, there are religious practices, for example meditation, that are believed to take part in enhancing the immune system. Studies of BIS and AIS, as well, may reveal conflicting or collaborating concerns on this matter.

Sources of Authority

The authorities in artificial immune systems used to be scientifically interested computer scientists, engineers, and algorithm developers. As the

research work has been increasing on this field, several associations (research groups) have emerged to promote research in this area of study. Among the most relevant and well-known organization is the IEEE Computer Society Task Force on Artificial Immune Systems ([IEEE Computer Society Task Force on Artificial Immune Systems](#)).

Ethical Principles

This discipline does not directly deal with living beings, but rather uses metaphors of biological immune systems. Ethical principles are the general principles from applied and theoretical sciences to provide solutions to theoretical and technological problems of human kind.

Key Values

The key value of AIS is to provide solutions to different kinds of problems that remain unsolved or that could be solved in more efficient ways by providing better performance than existing solutions.

Conceptualization

Nature/World

Nature is conceptualized as the constituent physical and biological elements that form the universe. World is the set of all physical elements in the earth.

Human Being

A human being is considered as a complex biological being endowed with special features that make him very efficient in problem solving and understanding and changing his/her environment for his benefit and those of his/her own species.

Life and Death

Life is conceptualized as the presence of special functions in natural systems that allow them to remain in its environment by

performing these primary functions. Death is the event that happens on a living being when it is no longer capable of performing its basic functions.

Reality

Reality is considered as the set of all elements in the universe that exist and can affect and interact with each other in real time.

Knowledge

Knowledge is a set of data, rules, and facts known about a particular system or process. Knowledge can be individualized or collective.

Truth

Truth is some factual knowledge about the world that can be verified.

Perception

Perception is some partial knowledge that any life or artificial being acquires from its environment through some special components provided for such task.

Time

Time is a reference measure that is used to keep track of the changes that occur in the world.

Consciousness

Consciousness is a life being's ability to know about itself and its role in the world and of being aware of the consequences of its actions.

Rationality/Reason

Rationality is an ability of human beings to analyze situations and make what they believe is the right decisions under those circumstances.

Mystery

A mystery is something for which there is no formal or scientific explanation.

Artificial Intelligence, General

Stan Franklin

Computer Science Department & Institute for Intelligent Systems, The University of Memphis, Memphis, TN, USA

Related Terms

[AI](#); [Artificial minds](#); [Computer science](#); [Machine intelligence](#)

Artificial Intelligence (AI) devotes itself to producing computer systems that act intelligently, solving problems in ways we would call intelligent if done by a human. One outstanding example was the AI system called Deep Blue in 1997, defeating world champion Gary Kasparov in a six-game chess match. Though running on a specially built computer and provided with much chess knowledge, Deep Blue depended ultimately upon traditional AI game-playing algorithms. The match with Kasparov constituted an AI triumph.

A second such triumph involved mathematics, which everyone would agree, requires intelligence. In a 1933 paper, E.V. Huntington gave a new set of three axioms that characterized a Boolean algebra, a type of formal mathematical system with important computer science applications. The third of these axioms was sufficiently complex as to be practically unusable. This motivated Herbert Robbins to replace this third axiom with a more usable one, and to conjecture that his new axiom set also characterized Boolean algebras. This Robbins conjecture soon became a famous unsolved mathematical problem that resisted the efforts of numerous human mathematicians for over half a century. The Robbins conjecture was finally proved correct, also in 1997, by a *general-purpose* AI automatic theorem prover called EQP (Equational Prover), producing a proof that mathematicians could read and agree to. In an area requiring intelligence where humans had failed, the AI system EQP, not designed for this particular problem, succeeded (McCune 1997).

A third such spectacular AI triumph occurred in 2011 when an AI system called Watson defeated three human champions on live TV in two rounds of the so popular intellectual game of Jeopardy. Watson's ability to answer complex questions posed in the same ordinary English heard by the human competitors depended heavily on its AI technology. Its AI natural language processing allowed Watson to understand the questions, as well as possible answers, from its knowledge base, while its AI heuristic search technology enabled it to find possibly correct answers more rapidly than its human competitors.

Less spectacular, but even more of a triumph for AI was the advent and wide commercial acceptance of knowledge-based expert systems, AI systems that captured and represented expert human knowledge and made it available to the user. Perhaps the earliest such commercially successful expert system was XCON (McDermott 1980), which saved millions of dollars for Digital Equipment Corporation by effectively configuring their VAX computers before delivery, rather than having DEC engineers solve problems after

their delivery. Other such applications followed, including diagnostic and maintenance systems for Campbell Soups' cookers and GE locomotives. A Ford Motor Company advertisement for a piece of production machinery stipulated that such a diagnostic and maintenance expert system be a part of every proposal. Expert systems constituted the first AI killer application.

The advent of video games led to a second AI killer application, the production of AI systems to control video game characters. The smarter, and more human-like, the characters, the better the game. Video game companies came to compete for the services of AI programmers.

Video game characters are one example of a type of AI system called software agents that are absorbing most of the attention of AI researchers. A software agent is autonomous in that, once programmed and turned on, it senses its environment and acts on it in pursuit of its own agenda. Autonomous software agents come in several varieties, most "living" in some kind of virtual, digital environment such as on the Internet. They autonomously perform a specified task, such as the "bots," that search the Web for new links to bring home to their search engine masters. Others, sometimes called avatars, have virtual faces or bodies displaying on monitors that allow them to interact more naturally with humans, as in intelligent tutoring systems. Still others, called conversational virtual agents, simulate humans, and interact conversationally with them in chat rooms, some so realistically as to be mistaken for human. Finally, there are the virtual agents as characters in computer and video games.

AI has come a long way since its inception in the summer of 1956. During its early days, AI researchers were intent of creating systems exhibiting human-level intelligence, including the ability to gather new knowledge on their own, to solve non-routine problems, and to learn new skills. It was not long before they discovered just how daunting and seemingly impossible such an enterprise really was. The field of AI rapidly changed course so as to devote itself to developing and implementing AI systems that produced intelligent behavior within some relatively narrowly defined domain such as those we have

described above. More recently (circa 2006), interest has reemerged in developing systems with a more general, human-like intelligence, and the research field of Artificial General Intelligence was born, with its own academic conferences and journal (Goertzel and Wang 2007). As yet, the enterprise still seems daunting, but no longer impossible, just difficult.

Since AI systems run on computers, AI can be considered a branch of computer science, and is typically found in computer science departments in universities. But the study of machine intelligence can also be used to shed light on human intelligence, giving AI a major intersection with cognitive science and cognitive modeling. A cognitive model provides a conceptual theory of how human cognition works, all the way from sensation and perception, through understanding and problem solving, to action selection and execution. Cognitive architectures, the computational implementation of such cognitive models are used on their science side to guide experimentations with humans, and on their engineering side, to control software agents and real-world autonomous robots.

So far, we have viewed AI as outsiders looking in. What can it do for us anyhow? If we changed perspective and view AI as would a student, a researcher, or a practitioner, we would find a world concerned with searching heuristically, with planning, with representing knowledge, with pattern recognition, with heuristic search, with natural language processing, with machine vision, with decision making, with machine learning, with autonomous agents, and with many other such arcane areas of study. AI is very much a technical field of study and practice (Russell and Norvig 2009).

Is AI a science? Well, yes and no, depending on how you want to use the word. In our often scientifically illiterate world, the term science is often, if mistakenly, used synonymously with technology. And as we have seen, AI is surely a technology. The insiders, the scientists themselves, would restrict science to empirical studies that seek knowledge from the real world through observation or experiment. Such usage would include such disciplines as physics, chemistry,

biology, psychology, and cognitive science, but would omit fields, such as mathematics, computer science, medical science, and the various engineering fields. Science pursues knowledge for its own sake and with the prescribed methods of observation and experimentation. These latter fields, while sometimes using science as a tool, have quite other aims and are not truly science. Where does AI fit within this scheme? In both camps. The modeling contribution of AI to cognitive science provides hypotheses, and thus guidance, for experimentation into human cognition, making this sort of AI a part of science. Chess players, expert systems, etc., belong to technology, but not to science.

AI is distinguished among other disciplines, and among other subdisciplines of computer science, by its major aims, to understand intelligence and to implement it in intelligent computer systems. Among other subdisciplines of computer science it can also be distinguished by its use of heuristics to seek good enough, rather than optimal, solutions to problems, and also by its willingness to take advantage of biological influences. The latter has led to such AI subdisciplines as artificial neural networks, genetic algorithms, artificial immune systems, and fuzzy logic.

AI is entirely concerned with science and technology and has nothing whatever to say concerning religion or AI's relevance to religion. The issue just never seems to come up. In the same way, AI is completely silent about the relationship between science and religion, or its relevance thereto, being only tangentially related to science and totally unrelated to religion. The relationship of science and religion seems to have no implications for the teaching of AI, for a career in AI, or for the role of the discipline in industrial information technology departments or in academic computer science departments. AI's role in the larger society is for the most part determined by commercial considerations, the usefulness, and value of AI systems. In addition, people most often find the very idea of an intelligent machine intriguing, and want to know more about it.

Though AI has produced its share of heroes, such as Alan Turing (the grandfather of the field), Herbert Simon and Allen Newell, John

McCarthy, and Marvin Minsky (collectively the parents), they are revered but not looked to as authorities. In its 50 years of existence, AI has always been a fast moving field, rapidly progressing both theoretically and practically. Its practical products are typically commercial and, thus, proprietary. The source of authority on this side of the aisle is the dollar. On the theoretical side, AI produces studies that are presented in numerous workshops and conferences, usually with published proceedings, and published in a wide variety of professional journals. One might say that this accumulated literature comprises the sole source of authority in AI, if there is any at all. Within AI, every assertion is subject to scrutiny, analysis, and question. Nothing is accepted by authority, because someone in authority claimed it, or because it was published in an authoritative journal. Textbooks, conference papers, journal articles may all be influential, but none are authoritative in the sense of being accepted upon its own say-so.

AI shares its key values with other academic and commercial disciplines. One must be honest in one's claims, one must not plagiarize, one must behave ethically, etc. Ethics also arises as part of the content of AI in two different ways. AI cognitive architectures model decision making in humans, which includes moral decision making. An entire issue of the journal *Topics in Cognitive Science* was devoted to "Cognitive Based Theories of Moral Decision Making," but made no mention of religion (Wallach and Franklin 2010). Also, during the formative AGI workshop (Goertzel and Wang 2007) a panel discussion seriously considered the ethical ramifications of creating an AGI agent with human-level intelligence or beyond.

AI takes a naturalistic and scientific world view, considering human beings as one species of animal when used to model either humans or other animals. AI does not speak of life, except to have given rise to the now quite separate discipline of artificial life. Of death, it does not speak at all.

AI does not concern itself with epistemology, the philosophical study of knowledge. It is,

however, vitally concerned with the representation of knowledge in computer systems, with knowledge representation being a major subfield of AI. How best to represent and use the various sorts of knowledge, perceptual, declarative, procedural, etc., is a primary occupation of many AI researchers and a secondary occupation of almost all of them. Not only knowledge-based systems, but AI systems of every variety, must employ representations of knowledge.

As is the case with knowledge, AI is concerned with truth not in a philosophical sense, but as it is employed in AI systems based on mathematical logic. Many AI systems use symbolic logic for knowledge representation and, so, face the issue of machine determination of the truth or falsity of propositions expressed within such systems. All these considerations are quite formal, being concerned with truth within the system and not with truth in the real world.

The situation is quite similar regarding rationality/reason. Many AI systems, using mathematical logic for knowledge representation, employ reasoning algorithms to derive new true propositions from the existing ones within the system, or in the case of AI agents, to optimize the selection of its next action. Such agents are referred to as rational agents.

The situation is again much the same with respect to time, concerns with which occur mostly in AI systems using temporal logic for knowledge representation. These systems are used primarily in the AI sub-areas of planning and scheduling. Time is typically to be reasoned with within the system.

Perception, the understanding of sensory input, is a central concern of that branch of AI called computer vision. Machine vision systems must recognize objects, identify individuals, understand events, etc. Also, AI agent systems face these problems with respect to their built-in sensory modalities. Of course, an AI-controlled autonomous real-world robot will have quite different sensors than an AI software agent. The digital senses of the latter may not even seem like senses at all.

AI agent systems are also occasionally concerned with consciousness, which is used

mostly in the sense of functional consciousness, almost synonymous with attention (Franklin 2003). Phenomenal consciousness is mostly ignored except for a new subfield of AI called machine consciousness, which has its own workshops and journal.

When producing broad, comprehensive architectures, the cognitive modeling subfield of AI often concerns itself with perception, knowledge, and reason, as well as occasionally with time and consciousness.

The term “mystery” never arises in the AI literature. There is simply no such issue to be considered. Nor do there seem to be other issues, themes, or concepts used in AI that are relevant to a discussion of the relationship between science and religion. With the exception of cognitive modeling, AI has little to say about science, nothing to say about religion, and nothing at all to say about their relationship.

Artificial Neural Network

Gómez González Daniel
Universidad Complutense De Madrid, Madrid,
Spain

An artificial neural network (with acronym ANN), usually addressed as neural network (with acronym NN), is a model used in the field of mathematics or computer science that is inspired in the structure and/or functional aspects of biological neural networks or human brain. A neural network consists of an interconnected group of artificial neurons or nodes, and it administers the information using a connectionist approach to computation. In most cases, an ANN is an adaptive system that changes its structure based on external or internal information that flows through the network during the learning phase. Modern neural networks are nonlinear statistical data modeling tools. They are usually used to model complex relationships between inputs and outputs or to find patterns in data.

Astrology

Nicholas Campion
University of Wales, Trinity Saint David,
Wales, UK

Related Terms

[Horoscope](#); [Prediction](#)

Description

Astrology claims that there is a relationship between celestial patterns and earthly events. The astrological world view holds that all things in the universe are interconnected, whether psychically, physically or both (Campion 2012a). Within this inclusive definition there are different philosophical rationales, religious affiliations, technical procedures, and attitudes to what the study or practice of astrology can achieve. Arguments about astrology's validity focus on the extent to which general principles of cosmic interconnectedness can be used to extrapolate the detailed rules which allow astrologers to reach precise judgments on human affairs. Astrology claims to yield different kinds

of information, from the correct times to plant crops or perform religious ceremonies, the diagnosis and treatment of disease, information about personality, knowledge of the future or the means required in the quest for personal meaning or salvation.

The principle justifications for astrology view it as functioning via either (a) a set of signs, usually sent by a divine entity, which may be read by the astrologer, (b) influences or causes, which might themselves be of divine origin, though manifesting in the natural world, or (c) correlations, in which events on earth may correspond in time to those in the heavens, but possess no causal relationship in the modern sense. The first justification may be defined as divination, the second as natural science, and the third finds textual authority in Platonic and Aristotelian philosophy, and the psychology of C.G. Jung, in which it is described as “synchronicity.”

Most cultures have an astrology in the sense that they endow the celestial bodies with meaning or use them for timing significant events (Campion 2012a). However, there are only three mathematically complex systems, which claim to be able to either predict the future or manage the present with exact detail. These are (a) the Meso-American (Mayan and Aztec), (b) the Chinese, and (c) the Western/Indian. The latter draws on Babylonian antecedents, with probable Indian, Greek, Persian, and Egyptian contributions, and reached its current level of technical complexity in Hellenistic Egypt in the first and second centuries BCE. In the modern world, only India, in which astrology is one of the six vedangas, the subjects necessary to a proper understanding of the Vedas, remains home to a popular, complex tradition which dates back in an unbroken lineage to the ancient world.

The primary technical tool of Hellenistic astrology was the horoscope, strictly defined as the degree of the zodiac rising over the eastern horizon but, in a looser sense, the entire diagram of the heavens cast for a particular moment: the earth is placed at the center, surrounded by the planets and selected other features, sometimes including stars, themselves located in the zodiac,

and 12 other divisions known in modern astrology as “houses” (Campion 2009a). Modern newspaper and magazine astrology columns are also known as horoscopes.

There are four primary divisions of practical astrology (Campion 2009b): (a) natal, in which a horoscope is cast for the time of birth, (b) electional, in which auspicious times are arranged to perform appropriate acts, including sacred rituals, (c) horary (previously interrogational), in which a horoscope is cast for the time that a question is asked, and (d) mundane (previously revolutions), in which history is analyzed and political events are forecast.

Prediction has, in most traditions, been practiced only in the context of a desire to change the future; determinism in astrology has usually been qualified by the notion that destiny can be negotiated. The active participation of the astrologer in the manipulation of time and space may be seen as a species of magic. The most recent innovation in the western tradition has seen the application of depth psychology and counseling to natal astrology. In contemporary psychological astrology, character analysis and advice-giving are seen as more important than predicting the future.

Self-identification

Science

Within the tradition opinion is divided. Some practitioners reject the term “science” altogether but, for those who use it, it can have two meanings. For some, astrology-as-science implies that it has a body of rules that are founded in self-evident truth. The term “divine-science” is sometimes used in this sense, pointing to a belief that the “science” can reveal the individual’s relationship with the divine, or that its rules are divinely sanctioned. For others, astrology-as-science suggests that astrology should be based on testable claims and empirical data. Among historians Babylonian astrology is often defined as a science on the grounds that it used rules of interpretation based on a clear logic. The term is less frequently applied to the astrology of later periods.

Religion

Opinion is divided. While many western astrologers would agree with historians that astrology originates in ancient religion, there is a profound hostility to the term among many modern practitioners (Campion 2012b). There are two main reasons. The first is that religion is commonly identified with belief and many astrologers are aware of skeptical arguments that objects of belief are automatically false. They prefer to justify their use of astrology on the grounds that they “know” it works, such knowledge being based on personal experience, a species of gnosis. The second reason is that many astrologers share the modern western rejection of “religion” as negative and repressive, in favor of “spirituality,” which is viewed as positive and liberating.

Characteristics

Astrology’s distinctiveness is rooted in its claim that its frequently intangible assumptions are based in the measurable motions of the stars and planets. As a practice which lacks any necessary belief in a Supreme Being, sacred text or single set of dogma, it can attach itself to any religion or ideology. There are few atheist astrologers, but there is no bar to being one.

Relevance to Science and Religion

Modern western astrology exists in a state of tension with science and religion.

Although the terms “science” and “religion” are usually rejected by astrologers, most feel that orthodox science and mainstream institutional religion would benefit from the astrological world view and, in some deterministic accounts, will, in the near future, recognize its value.

Sources of Authority

Astrologers derive their authority from personal experience and a body of literature mainly handed down since Hellenistic times. There are

respected authors but no “scriptural” or sacred texts. Most texts are teaching manuals, which give instruction in reading horoscopes but there is very little philosophy. This is usually gleaned elsewhere, from whatever ethical or religious tradition with which the individual astrologer is affiliated.

Ethical Principles

Astrology’s interpretative rules have no inherent morality, although modern astrology tends to be guided by the New Age “self-ethic,” assuming that personal spiritual or psychological development of necessity leads to a higher standard of ethical behavior. Classical and medieval astrology was heavily influenced by notions, inspired by Platonism and Stoicism, that acts of either prediction or magical engagement with the cosmos are only possible if a virtuous life is followed.

Key Values

Astrology generally holds that harmonization of individual and collective behavior with cosmic patterns is inherently desirable and bound to bring beneficial consequences.

Conceptualization

Nature/World

Astrologers generally see the world as alive and a source of wonder. Nature tends to be romanticized as special, spiritual, and possessing healing qualities.

Human Being

Human beings are thought of as a “microcosm” of the celestial “macrocosm” containing an inner cosmos, often represented through planetary or zodiacal correspondences with parts of the body.

Life and Death

The majority of modern practitioners accept the reality of reincarnation and the wheel of death

and rebirth, a belief which was also present in Hellenistic astrology through Platonic influences and is standard in Indian astrology.

Reality

Reality is often perceived as being “psychic” rather than material, evidence of the legacy of Platonic Idealism in the tradition.

Knowledge

A high value is placed on personal experience and “intuition” as sources of knowledge. Many (but not all) modern astrologers claim that the techniques of astrological interpretation have no intrinsic objective validity but that each astrologer finds the techniques which work for them.

Truth

There is a general belief in the existence of absolute spiritual truths, but modern opinion is divided on whether astrological “truths” are themselves absolute, or only relative.

Perception

Astrologers generally believe that astrology can help them perceive truths which are concealed from non-astrologers.

Time

Time is perceived as broadly cyclical in that general conditions recur in complex patterns and in line with celestial movements, but usually without exact repetition.

Consciousness

Most (but not all) astrologers are Idealists, in the Platonic sense, believing that consciousness is prior to matter.

Rationality/Reason

Although the use of reason was a key feature of the Platonic and Stoic schools of thought in Hellenistic astrology, modern astrologers tend to polarize “intuition” with rationality, regarding the former as a reliable source of knowledge and the latter as likely to obstruct self-knowledge.

Mystery

The function of astrology is to give mystery a daily relevance by using symbols to relate feelings of mysterious, numinous, cosmic wonder to specific conditions, from spiritual states to daily activities and physical objects. Astrologers report that the experience of astrology “working” can itself lead to a sense of numinous wonder, and an awareness of the mystery of the cosmos.

Special Themes

Natural and Judicial Astrology

An important distinction between two kinds of astrology separates Natural Astrology from Judicial Astrology (Campion 2009). Natural Astrology is based in natural influences, seasonal effects and cyclical phenomena which can be understood as objective phenomena. Judicial Astrology assumes that the astrologer’s interpretation is necessary in order to judge the outcome of any scenario. At its extreme there can be no astrological phenomenon without the presence of the astrologer to interpret it.

The distinction between Natural and Judicial astrology is paralleled by that between two theories about the construction of the rules of astrological interpretation (Brown): either they are based on empirical observation of the coincidental repetition of terrestrial and celestial events, or they are derived from systems of imaginative word-association, metaphor and metonymy. In the majority of cases the two theories are combined.

Associated with the distinction between Natural and Judicial astrology is the question of whether astrology investigates the objectively real world, measuring personality and predicting events, or whether it is a symbolic language concerned with the construction of meaning (Campion 2012a).

Pseudoscience

The term pseudoscience is applied to astrology in two different senses. One is that its claims are untestable and hence non-falsifiable. The other is that its claims have been tested and have universally been falsified. However, there are two

problems with these assertions. The first is that they are mutually contradictory: the former claims that astrology is untestable, and the latter that it has been successfully tested. The second is that the results of scientific testing are mixed and, while some results are negative, others are positive and have not been refuted. The description of astrology as a pseudo-science may therefore be applicable in specific instances but cannot be applied to the practice as a whole. Protagonists for astrology, like critics, are divided between those who think that astrological claims are testable and those who argue they are not. Claims of testability are based on the idea that astrology exhibits a deterministic order in the cosmos (which, however, does not contradict the presence of variety and individual choice). The challenge to testability rests on a number of claims: (1) all astrological phenomena are unique and replicable experiments are therefore impossible, (2) individuals have free-will and the manner in which astrological indicators at birth manifest in life events is therefore inherently uncertain, (3) some traditions of astrology, sometimes characterised as magical, require manipulation of the world, rendering experimental testing impossible, (4) astrology is a system of interpretation which has no necessary basis in astronomical measurement and (5) astrology may include divine intervention, as in India, rendering testability inherently impossible.

Scientific Research into Astrology

The earliest known systematic attempt to gather empirical data on astrology dates back to Assyria in the seventh century BCE in the compilation of the co-called “Diaries.” The first attempts to test astrological claims date to Johannes Kepler’s (1571–1630) experimental political and meteorological forecasts. Consistent attempts to test astrology date only to the 1950s–1980s. There are three notable examples. The Eysenck-Mayo research (1982) matched zodiac signs to the Eysenck Personality Inventory and concluded that individuals born with the Sun in Aries, Leo, Sagittarius, Gemini, Libra and Aquarius exhibited extroverted qualities, while those born with the Sun in Taurus, Virgo, Capricorn, Cancer, Scorpio and Pisces

were introverted. It was later concluded that the positive results were due to self-attribution in which participants rated themselves in Eysenck’s system according to their astrological profiles. The Carlson research (1985) asked astrologers to match individuals to the California Personality Inventory. The results were negative for astrology but Carlson’s methodology and results have since been challenged (e.g. Currey 2011). The Gauquelin research (1988) had three components. First, the “Character Trait-word Hypothesis” identified astrologically-appropriate descriptions for notable individuals in reference books. This has been challenged on the grounds of selection-bias. Second, the “Heredity Hypothesis” proposed that children tend to be born with the same prominent planets as were their parents. Gauquelin concluded that the phenomenon ceases when birth is induced and the Heredity Hypothesis has neither been replicated nor refuted. Third, the “Eminence Effect” demonstrated that individuals who achieve eminence in sport, politics, the army, theatre, science and literature tend to be born with certain planets rising or culminating. Only the “Mars Effect,” which links sporting achievement to the planet Mars, has been replicated, with claims of both negative and positive results (Ertel and Irving 1996).

Substitute Religion

Both religious and secular critics have defined astrology as a “substitute” or “quasi” religion. The argument is problematic because it assumes that it is possible to identify a “true” or “genuine” religion as opposed to a “false” one. In India, where astrology is one of the vedangas, necessary for the understanding of the Vedas, the sacred texts, and the planets are still linked to gods and goddesses, astrology is an integral part of religion.

New Age

Astrology is often defined as a New Age religion (Campion 2012b). However, while modern astrology is popular in New Age culture and has been shaped by New Age ideology, the term should only be applied in particular circumstances, such as the impact on recent developments in astrology of the belief that a New Age is imminent.

Description

The discipline featuring as “science of the stars” (*‘ilm al-nujūm*) in medieval classifications of knowledge in Islam actually consists of three parts: (1) astronomy (*‘ilm al-falak*, literally “the science of the sphere” or *‘ilm al-hay’a*, “the science of the exterior shape”), which is concerned with the observation and the mathematical description of the celestial bodies and their movements; (2) a science, otherwise unnamed, to do with tables, calendars, and the calculating of eras; (3) astrology (*‘ilm aḥkam al-nujūm*, literally, “the science of the celestial decrees”), which deals with the prediction of events on earth on the basis of indications from the celestial revolutions (Kennedy 1998; Nallino 1944; Saliba 1982).

Like most other fields pertaining to the “rational sciences,” Islamic astrology is largely indebted to ancient traditions, especially from India, Persia, and Ancient Greece as these traditions were introduced into Islam as part of the translation movement of scientific works initiated in early Abbasid times (Caiozzo 2003). Ptolemy's *Tetrabiblos* remained for long the great model of astrological treatises.

Although it is characterized by a high level of sophistication in its form and a certain abstruseness in its methods of computation, astrology as developed in Islam by its most famous representatives (Māshā'allāh, Abū Ma'shar, the Ikhwān al-Ṣafā', among many others) lays on a few basic assumptions inherited from the Greeks: the geocentric representation of the world, the cyclicity of time and the circularity of all celestial movements, the conception of man as a microcosm and, conversely, that of the universe as a big man, the general sympathy between all elements in the creation, the ontological barrier between the perfect, divine and uncorrupted world of the spheres, and the sublunary world regarded as the place of coming to be and passing away (Sezgin 1979; Ullmann 1972). It appears that the Neoplatonist theory of emanation, by postulating the existence of a process whereby all beings are said to have flowed or “emanated,” like a light, from the original principle, largely contributed to the acceptance of astrology among the philosophical and scientific circles of Islam. [Science of the stars](#)

Islamic astrology borrowed an important theory of conjunctions between Saturn and Jupiter, supposed to induce replacements of individuals on the royal throne, shifts of dynasties from one nation to the next, and changes of empires and religious confessions (de Callatāy 1996; Pingree 1968).

Relevance to Science and Religion

Along with other occult disciplines in Islam such as divination or magic, astrology occupies an interesting position in the scholarly area called “science and religion.” Although not explicitly condemned by the Qu’rān, the practicing of astrology was constantly perceived as dangerous and therefore rejected by the traditionalists of Islam, most notably by Ghazālī and Ibn Taymiyya. In his “On religions and sects,” a well-known treatise of heresiography, Shahrastānī despises as followers of a pseudo-religion all those who, like the members of the pagan sect of Ḥarrān, vowed a cult to the heavenly bodies and thought our lives are influenced by them. In spite of this, astrology never ceased to be practiced and regarded as a genuine science by many (Lemay 2000). To various Shī’ite branches, especially among the Ismailis, the theory of astrological cycles was used as a powerful instrument in order to justify Messianic expectations. But astrology also appealed to those who were supposed to impersonate the strict Sunni orthodoxy. Thus, for instance, al-Manṣūr asked a team of astrologers of his time to cast the horoscope of the foundation of Baghdad to make sure the new capital was founded under the best possible circumstances.

Description

Astronomy is the study of luminous celestial objects, of the dark intervening regions of space, and of the observable Universe as a whole. It is primarily an observational science, seeking to

measure and quantify the physical properties of the known constituents of the Universe, and to discover previously unknown celestial objects or phenomena. Astronomers investigate how cosmic objects originate, change, interact, move, and radiate. Theoretical studies, analytical models, and numerical simulations with computers are also employed to help understand these processes. Most significant astronomical discoveries have been accidental and serendipitous. They are the result of using new technology and novel telescopes that extend our vision to places that are not accessible to direct observation, enabling us to “see” the invisible and permitting us to look at the Universe in new ways. Larger and larger optical telescopes, operating at the visible wavelengths we detect with our eyes, have pushed the boundaries of the known Universe beyond our stellar Milky Way, resulting in the discovery of the expanding galaxies, rushing away from us and each other with speeds that increase with their distance. None of these receding galaxies can be seen with the unaided eye. Modern optical telescopes permit detailed scrutiny of the composition, distance, mass, size, position, and motion of the stars and galaxies, in conjunction with spectroscopy and digital detectors, such as the charged-coupled device. These instruments have also recently been used to detect miniscule, periodic stellar motions caused by large planets revolving in unexpected closeness to nearby stars. Smaller telescopes and cameras aboard spacecraft have been hurled past the moons and planets to reveal diverse and unexpected worlds. Ground-based radio telescopes have been used to discover and characterize interstellar hydrogen atoms, giant molecular clouds, pulsars, radio galaxies, quasars, and the cosmic background radiation. X-ray telescopes, lofted above our obscuring atmosphere with rockets and satellites, have been used to discover ten million-degree radiations from objects such as the Sun’s corona, black holes, and intergalactic space in galaxy clusters. Satellite-borne telescopes operating at gamma ray and infrared wavelengths are also making new discoveries, such as the extraordinarily energetic gamma-ray bursts and the infrared heat of protoplanetary disks.

Self-identification

Science

Modern astronomy self-identifies as a science that observes, measures, and quantifies the known physical constituents of the Universe outside Earth, often looking at them in new ways. It assumes that these celestial bodies obey identical physical laws to those on Earth, and uses these laws to explain them. Such explanations are tested and verified through predicted observable consequences.

Religion

Although modern astronomy is not identified as a religion, it has aspects that might be called religious. Astronomers believe, for example, that there is much more to the Universe than is presently known, and that there are hidden patterns and unknown phenomena that await our discovery. Astronomers participate in an endless search for these vast, previously undiscovered aspects of the Universe, often with a sense of awe and wonder. Like religion, astronomy provides us with a sense of something larger than ourselves, transporting us to distant realms far beyond our immediate material world and hectic lives and helping us connect with the immensity of the Universe.

Characteristics

Astronomy is a nonexperimental science in that celestial bodies cannot be taken apart or manipulated by controlled experiments in terrestrial laboratories, and astronomical explanations of cosmic phenomena can only be verified by passive observations. Astronomers study matter in the Universe under extreme conditions of temperature, pressure, or density that cannot be achieved on the Earth.

Relevance to Science and Religion

Astronomy operates under a faith that objective physical laws, which are verified by experimental and observational tests on the Earth, can explain

physical objects throughout the Universe. Like religion, astronomy often seeks a deeper understanding of phenomena that can operate beyond the range of known perception.

Sources of Authority

The ultimate source of authority in astronomy is peer review by repeated observations and predictions. Any astronomical discovery, or explanation of it, must be tested and verified by decisive observations of predictable consequences that are shown to be true or false.

Ethical Principles

Astronomers are skeptical, taught to question any discovery and to test it by significant observations, and they are trained to employ personal detachment and uncompromising honesty. They focus on the predictable, repeatable aspects of the observable Universe, and their results are either right or wrong, either verified or falsified by new observations.

Key Values

The key values of astronomy are the discovery and physical explanation of celestial bodies throughout the observable Universe.

Conceptualization

Nature/World

Astronomers regard nature as equivalent to the observable physical world outside Earth, although the natural terrestrial world is used as a foundation for physical laws thought to be applicable throughout the Universe. Astronomy uses telescopes to investigate all detectable celestial bodies, which most likely amount to just a modest observable fraction of nature, of the vast Universe. Nature is supposed to include both known and currently unknown cosmic objects and phenomena, either perceptible with

today's astronomical instruments or now unseen and detectable by future instruments.

Human Being

Astronomy does not normally consider either human beings or the pains and pleasures of human life. Such topics are thought to be outside the domain of astronomical inquiry.

Life and Death

Astronomers and astrophysicists have shown that our planet and everything on it are composed of elements synthesized either in the nuclear crucibles of stars that exploded into space before the Earth and Sun formed or before that, during the first moments of the Big Bang that gave rise to the expanding Universe. Despite our ability to pry living things apart, identifying their atomic, chemical, and molecular constituents, which can often be found outside Earth, no one has discovered the spark of life, showing how inanimate matter could have been transformed into a living thing, either on our planet or elsewhere. Astronomers forecast that life on Earth will not last forever, and that the entire human race is scheduled for extinction in a few billion years when the brightening Sun will vaporize the Earth's oceans.

Reality

To an astronomer, the real Universe consists of the currently observable one, but they often believe in a yet undiscovered, invisible reality that lies beyond the visible one and includes all that exists. Known celestial bodies, with well-defined, observed physical characteristics, are thought to be real, but so are other ill-defined celestial phenomena such as dark matter, dark energy, and supposedly empty space.

Knowledge

Astronomers regard knowledge of the Universe as a cumulative, ongoing process of the discovery of its ingredients and behavior, and coin new terms to describe newly discovered celestial objects, such as black holes, blazars, pulsars, and quasars.

Truth

Astronomers believe in an objective, scientific truth verifiable by decisive observations and

significant tests. To them, truth in the extraterrestrial world consists of celestial bodies or phenomena that may be repeatedly and consistently observed.

Perception

Astronomers use new technology and novel telescopes to extend the capacity of their physical senses, thereby perceiving, becoming aware of, and eventually understanding otherwise invisible physical objects that lie outside the Earth and are inaccessible to direct observation. These perceptions are repeatable, and can be obtained by anyone using the same or similar instruments.

Time

Because light travels at a finite speed, astronomers look back into time when observing distant objects. As long as light passes through empty space, encountering no atoms or electrons, it can persist forever, bringing its message forward from the beginning of time to the end of the Universe. Powerful telescopes are therefore used as time machines to see objects as they were in the past, when their light was first emitted. They are seen as they were then and not as they might be now. The expanding Universe has a history, which astronomers decipher, but this only applies to times after the Big Bang. No astronomer, astrophysicist, or cosmologist knows for certain what happened before the Big Bang about 14 billion years ago, and time might have even begun with this creative event.

Consciousness

To an astronomer, consciousness is the mental awareness of the surrounding Universe, involving the perception of any physical object that exists, both visible and invisible.

Rationality/Reason

An astronomical concept is rational if it is grounded in direct, verifiable observations of celestial bodies, and explained using accepted physical laws. Speculative explanations of cosmic phenomena, including those based on mathematical equations, may not be fully rational in an astronomer's sense if they have not been decisively tested by significant observations.

Mystery

The entire Universe is regarded as a great hidden mystery awaiting discovery and understanding, and its known constituents may also have mysterious aspects that remain to be examined and understood.

Relevant Themes

There are many critical, unexplained aspects of the Universe that lie outside the domain of direct astronomical observations, and are concerns of religion. They include the origin and fate of the Universe and life within it. No astronomer, astrophysicist, or cosmologist knows for certain what happened before the Big Bang, or how the observable Universe came into being, and they do not know if life originated from inanimate matter, or exactly what might have provided the spark of life on Earth. And owing to the recent discoveries of dark matter and dark energy, which we know almost nothing about, the eventual fate of the observable Universe remains unknown, despite the fact that distant galaxies are now accelerating into invisibility.

[Cosmology in the Jewish culture](#); [Jewish cosmology](#); [Jews and the study of the universe](#); [Judaism and the study of the universe](#)

The opening chapters of the Book of Genesis in the Hebrew Scriptures draw a very general but simple picture of what the universe looks like. It is that picture that frames subsequent interpretations of the narratives within the Jewish Bible and guides their interpretation. The cosmology of Genesis divides all of space into two distinct regions, one governed by light (called “day”) and the other guided by dark (called “night”). Similarly, this occupied space is divided into two regions. There is a central disk of earth, surrounded by a ring of water, above which is a ring of fire. The one deity, named “Elohim,” is the sole active agent in this story of creation. He wills divisions in the space of the earth forming waters below the disk of the earth as well as waters above the disk (called “seas”). Furthermore, he stretches out something called a “firmament” (raqiya’ in Hebrew, which literally means a stretcher) to isolate between the earth and its upper waters on the one hand and the ring of fire on the other hand a bubble (so to speak) of air, called “the sky” (ha-shamayyim in Hebrew, a word that suggests a compound substance of fire and water). The sky divides the upper waters into “seas” and rests upon a now waterless surface of earth called “dry lands”. Together, this two-part rotating space (day and night) houses two distinct spatial territories (earth and sky) that are home to all living things. The inhabitants of the sky are those objects we would recognize as celestial bodies – stars as well as planets, while the inhabitants of the earth include living things that swim

in the waters, fly above the earth, and either crawl or walk upon the surface of the earth.

The above conception of the cosmos undergoes radical change as it is interpreted by the early rabbis in their commentaries on the biblical text. These commentaries are called “midrash.” Without explicitly referencing their scientific sources in the Greco-Roman world, scientific sources (i.e., sources from natural philosophy) are used to transform biblical cosmology into a rabbinic cosmology that reflects a form of synthesis of the early Hebrew culture with the contemporary Hellenistic culture. With respect to cosmology, the rabbinic view of the cosmos has the following distinctive features: First, the original light of creation disappears from the cosmos and is seen rather as something reserved for a world to come when this world comes to an end, a light that early modern utopians and messianists will identify with “enlightenment.” Second, to the three elements of the biblical cosmos – earth, fire, and water – the rabbis add the fourth element of Greco-Roman science – air. Third, the two regions of reality – earth and sky – coalesce into a single region called “this world,” which is opposed to a hoped for vision of another, presumed better “world to come.” Fourth, the mover of the biblical cosmos, called “God’s wind,” becomes two distinct entities – God (Elohim) and spirit (Ruach) of God, and the spirit increasingly becomes associated with aspects of God through whom communication between God and humanity is transmitted. Whereas the biblical text speaks only of God, who rules all creation through commandments, the rabbis increasingly diversify God’s functions, each reflected by different divine names – God (Elohim), the Lord (YHWH), the Presence (Shekhinah), the Place (ha-Makom), etc. What are the ontological references of all of these names will become a major theological issue for subsequent rabbinic Judaism no less than it is for the offshoots of this early Judaism – Islam and Christianity.

It is the medieval Jewish (as well as Muslim and Christian) philosophers who work out in detail this synthesis of biblical and hellenistic cosmologies that becomes the authoritative view

of the cosmos in subsequent Jewish, Muslim, and Christian philosophy. This synthesis is formulated between the twelfth and fourteenth centuries. It reflects the best of Aristotelian-based empirical astronomy synthesized with the best of Platonic-based natural theology as the context for a radically non-literal interpretation of what the creation accounts in the Hebrew Scriptures really mean. The composites of the now four elements are defined by what they are rather than by what they do, and while their function in a sacramental food chain continues to describe them, it is no longer part of the expression of who and what they are. In other words, although sacramental food continues to have special importance in the spiritual life, it ceases to be in any sense near as important as a scientific category of animal classification. Finally and possibly most importantly, “nefesh” ceases to mean just breath and comes to mean a nonphysical entity called “soul.” The study of “nefesh” defines a radically distinct field of scientific or naturalist study, the field of psychology. Whereas physics and astronomy study objects that are material, psychology studies objects that are spiritual or mental, where material and physical are closely associated and spiritual and mental are closely associated, but increasingly the two intellectual fields of study are seen to share little in common.

This medieval synthesis of rabbinic dogma is shattered by the new sciences of modernity. In fact, it can be argued that the demands for conceptual synthesis between the past and present science are so radical that, unlike the transition from biblical to Hellenistic, no synthesis is possible. Whatever is the case in theory, in actuality, no synthesis has yet succeeded. Rather, the tendencies are to affirm one over the other (the modern scientific over the traditional Jewish cosmology or vice versa), to radically separate the two (claiming that cosmology is a scientific question for which Jewish thought has no relevance or that rabbinic tradition guides our view of the cosmos and in this context what science says is irrelevant) into absolutely distinct epistemic domains. The most dramatic separations between the two cosmologies have to do

with (1) the age of the cosmos, (2) the nature of the cosmos, and (3) the causal principles of the cosmos.

First, if Biblical time references are taken literally, then the age of the cosmos will turn out to be something like what the rabbi’s calendar marks as the age of the universe, which as of 2009/2010 A.D. is 5,770 years old. In contrast, physical cosmology suggests something like what is called a “hot big bang model” according to which the universe is 13.7 billion years old. Now this is a quantitative difference so great that it suggests that the two conceptions of the universe are different qualitatively.

Second, all premodern views of the cosmos posit a universe sharply distinguished by kinds. Things are not all the same; there are real principled differences between entities. However, in modern cosmology, the distinctions collapse. In fact – in a spirit totally coherent with modernity’s adoption of an inherent value in democratic forms of government – everything is in fundamental, natural components the same. Irrespective of the particular cosmology employed – be it biblical or medieval – there is a persistent belief that differences matter – between humans and other species as well as between Jews and other nations. However, according to modern physical cosmology, everything that has ever existed in the past, or exists in the present, or will exist in the future, has its origin in a vast sea of totally undifferentiated plasma. In the moments following the beginning of everything, as the universe gradually cools and expands, forces emerge – first gravity and the strong force (at about 10^{-43} – 10^{30} of a second after the big bang of creation), followed by the weak force and electromagnetism (at about 10^{-12} – 10^6 of a second after creation), followed by the first physical entities. At 3 minutes and 20 seconds after the creation, atomic nuclei emerge from energy soup, leading to distinct fundamental particles. Some 150 million to 1 billion years after creation, there form stars and galaxies. Some 8 billion years ago, our solar system formed out of the particles in our galaxy, which, in turn, gave rise some 2.3–2.4 Ma ago to the first members of genus homo on planet earth,

and then, a mere 400–250 thousand years ago to the first *Homo sapiens*.

Third, and probably most importantly, the kinds of causal principles admissible in explaining change within the cosmos are different. Aristotle had listed four kinds of causes – formal, material, efficient, and final – and insisted that any valid scientific explanation would involve a synthesis of all of them. The biblical narrative is easily adaptable to Aristotle’s classification for the biblical text speaks of efficient causes wedded to final, i.e., teleological causes (viz., distinct divine speech acts as efficient causes wedded to proclamations that what God says is “good” (tov) as final causes). But modern cosmology, like modern science in general, admits only mechanical causes. Whereas the biblical and rabbinic cosmology interpreted all events as purposeful, modern cosmology interprets all events as purposeless, viz., as expressions of natural accidents.

All of these differences can and have been reconciled in Jewish religious thought in one way or another with one single exception. Whereas the standard scientifically oriented interpretations of the cosmos consistently tend to see the universe as a product of mechanical forces operating on what is ultimately a cosmic accident, the rabbinic understanding of the universe as God’s creation demands that the cosmos be understood as something “good,” i.e., that exhibit an ordering that is subject to moral judgment.

Description

Civilizations in which Islam was the religion of either the rulers or the majority of the population were the cultural context for several hundred years of remarkable achievements in astronomy. While astronomy was sometimes in a conversation with Islamic law, speculative theology (*kalām*), and *Qur’ān* commentary and

while at other times Islamic astronomy served clearly religious applications (such as the determination of the direction and times of prayer (*qibla*)) (King 2004/2005, Vol. 1), Islamic astronomy was driven by more than religious concerns. Astronomy in Islam aimed at an increasingly precise description of the universe, whether in the domains of physical consistency of observations, more accurate observations and tables, or theories' predictive accuracy.

There is evidence of astronomical activity and translation of astronomy texts under the Umayyads (661–750); both activities intensified under the Abbasids (750–1258). Recent scholarship has attributed the rise of science in Islam to practical considerations rooted in the engineering, architectural, and computational needs of the expanding empire as well as the political prestige associated with patronizing science and using astrology publicly (Saliba 2007, pp. 25–72). Older accounts had paid more attention to wholly intellectual motivations, including religious exhortations to seek knowledge. The earliest astronomical texts to be transmitted and translated were astronomical handbooks with tables (Ar. *zīj*, plural *azyāj*).

Frequently, practical applications spurred theoretical advances and further translations. For example, in the ninth century, the practical application of *qibla* calculation led to developments in trigonometry. And after the al-Ḥajjāj ibn Maṭar translation of Ptolemy's *Almagest*, the caliph al-Ma'mūn (d. 833) patronized observations that assessed and improved parameters such as the length of the solar year, the obliquity of the ecliptic, and the precession of the equinoxes (Sayılı 1960, pp. 51–87; Charette 2006, p. 125). All of these observations had applications in calendar calculations and astrology and affected the physical models proposed to represent celestial motions. A subsequent *Almagest* translation included improved values for those parameters; even Ḥajjāj's translation had improved Ptolemy's parameters (Saliba 2007, pp. 79–80). Major observational work continued in the tenth century. As was the case previously, rulers' interest in astrology, an application of a *zīj*, was a motivation. For instance, the Buyid ruler 'Aḍud al-Dawla (d. 982)

studied astronomy and patronized astrology, along with his descendants, an impressive program of observations (Sayılı 1960, pp. 105–109; Charette 2006, pp. 127–128 and 133). Beginning in the tenth century, astronomers in Andalusia and North Africa began to develop models for precession and variations in precession (trepidation) (Comes 1996).

The prominence of astrology in Islamic civilization among political, intellectual, and, occasionally, religious elites elicited various reactions. Some of these reactions addressed astrologers' inability to produce accurate predictions. But others targeted astrology's theoretical dependence, particularly after the ninth century, on *falsafa*, philosophy in the Hellenistic tradition. Astrological predictions also had religiously objectionable implications for personal responsibility and understandings of divine foreknowledge. As a result of these debates about astrology, astronomers began to distinguish their science (increasingly known as '*ilm al-hay'a*') from judicial astrology and refashioned astronomy's relationship with *falsafa* (Saliba 2007, pp. 78–79, 174–176).

The need for patronage meant that astrology never disappeared as an application for astronomy. Even al-Bīrūnī (d. c. 1048), an astronomer who paid little heed to *falsafa* (Ragep 2001, pp. 58–59), wrote a text on astrology for the daughter of his patron. Bīrūnī's most famous work was his *al-Qānūn al-Mas'ūdī* (*The Mas'udic Canon*) a handbook of astronomy with tables that reflected his own observations as well as his extensive familiarity with the work of others. He also wrote works on trigonometry and on transits. His *India*, in which astronomy was only a single topic among many, was a masterpiece of ethnography.

By 900, Ptolemy's geometric and physical models to account for the observed positions of the planets had become dominant in Islamic civilization. One of Ptolemy's (fl. 125–150 C.E.) insights had been to determine, mathematically, the point about which a planet's mean motion was uniform. This point came to be known as the equant. Because the equant was not the center of an orb (or the center of the Earth), and because Ptolemy accounted for a planet's mean motion with an orb, the existence of the equant was

physically and philosophically inconceivable since orbs had to rotate uniformly about their centers. Aiming for a more accurate picture of the cosmos, Ibn al-Haytham's (d.c. 1040) *Doubts Against Ptolemy* (Ar. *al-Shukūk 'alā Baṭlamyūs*) catalogued this and other inconsistencies in Ptolemy's work (Saliba 2007, pp. 173–179).

Scientists associated with the Marāgha Observatory in Azerbaijan, such as Mu'ayyad al-Dīn al-'Urdī (d. 1266), Naṣīr al-Dīn al-Ṭūsī (d. 1274), and Quṭb al-Dīn al-Shīrāzī (d. 1311), developed innovative models, consisting entirely of orbs rotating uniformly about their own centers, that accounted for the available observations. In so doing, these astronomers removed the physical and philosophical inconsistencies of the equant point. Ibn al-Shāṭir (d. 1375) an astronomer and mosque timekeeper from Damascus continued the intellectual project of the Marāgha astronomers (Saliba 2007, pp. 131–170); Ibn al-Shāṭir's models resurfaced in Copernicus' *De Revolutionibus*, having been transformed into heliocentric models (Saliba 2007, pp. 193–232). Observations were an important part of the research associated with Marāgha, and as astrological forecasts were one motive for Hülegü's patronage, better observations would mean better forecasts (Sayılı 1960, p. 202). But astronomers associated with Marāgha also related observations to theoretical concerns. Al-Maghribī (d. 1283) carried out observations to find new parameters for the solar model, which was crucial for timekeeping. Maghribī also wrote on astrology. Ṭūsī's *Zīj-i İlkhānī* (*The Ilkhanid Astronomical Handbook*) contained a new value for the precession of the equinoxes, a parameter that would help astronomers calculate future celestial positions. Though the Ptolemaic solar model did not suffer from the difficulty of the equant, Ibn al-Shāṭir proposed a new solar model which better fit the available observations.

Theoretical and observational activity continued at the observatory in Samarqand in the fifteenth century under the leadership of Ulugh Bey (d. 1449). At Samarqand was a *madrasa* with science as part of the curriculum (Fazlıoğlu 2008, pp. 3–68). The instruments at Samarqand were on a large scale and were the

model for later observatories, such as the one at Jaipur. In the sixteenth century, Taqī al-Dīn ibn Ma'rūf used a comet to predict military success for the Ottomans (Sayılı 1960, pp. 289–305).

Astronomy became part of a tradition of religious scholarship not only because of the emerging division between astronomy and astrology but also because religious texts, from early on in Islamic civilization, paid attention to scientific developments. Early *Mu'tazilī kalām* texts, for instance, argued implicitly against the emerging *falsafa*. Al-Ghazālī (d. 1111) subjected science and natural philosophy to a sustained critique in *The Incoherence of the Philosophers* (Al-Ghazālī 1997/2000, pp. 166–177). *Mutakallimūn* (practitioners of *kalām*) did not aim to advance astronomy, but their arguments forced astronomers working in a religious milieu to couch more carefully the physical foundations of their own science. In the following centuries, *mutakallimūn* and *Qur'ān* commentators incorporated astronomical material into their own treatises (Morrison 2007, pp. 95–125; Sabra 1994, pp. 34–42). Once Ghazālī had pointed out the weaknesses of *falsafa*, the theoretical aspects of astrology, such as the idea that the heavens were a cause (though not an independent cause) of terrestrial events, found their way into some *Qur'ān* commentaries. Many of the astronomers associated with Marāgha (e.g., Ṭūsī, Shīrāzī, and Nizām al-Dīn al-Nisābūrī (d. c. 1330)) achieved recognition for their writings on religious subjects. Perhaps the culmination of scholars pursuing both scientific and religious subjects was 'Alī Qushjī's proposal for an astronomy founded on axioms derived wholly from observation and mathematics and not at all from natural philosophy as had been the case in the past (Ragep 2001, pp. 61–63).

Astronomy became part of a tradition of religious scholarship also because astronomy could enhance one's appreciation of God's creation of the cosmos (Ragep 2001, p. 63). Certain religious scholars introduced a skepticism about human perception to undercut the authority of astronomers (Morrison 2007, pp. 108–112). That skepticism, though, pitted itself against the ability of astronomy to enlighten Muslims as to the wonders of God's creation. One astronomer

working in a religious milieu, Nīsābūrī, used his relative confidence in knowledge derived from astronomy to convey a sense of wonder and mystery at all that he did not know. More important, Nīsābūrī drew a parallel between patterns of reasoning in Islamic law and patterns of reasoning in astronomy (Morrison 2007, pp. 70–72).

There was no astronomy unaffected by Islam to compete with *‘ilm al-hay’a*, but there was a competing astronomy based entirely on revealed sources (Heinen 1982). Astronomy affected Islam and vice versa. But astronomy in Islamic civilization and Islam still had, in the end, different sources of intellectual authority. Astronomy was classified apart from sciences such as Islamic law or *Qur’ān* commentary for the source of authority was the intellect not revelation. The intellect could be authoritative if the science contained nothing religiously objectionable. Matters of intellectual authority, the position of science in religious scholarship, and religious objectionability are the ways in which astronomy in Islamic civilization is relevant to a broader discussion about religion and science. Matters of intellectual authority are, then, bound up in how astronomers in Islamic civilization conceived of knowledge.

Description

Astrophysics is the application of the known laws of physics and/or theoretical models to understand

the known contents of the Universe, such as planets, stars, and galaxies, whose discovery and quantitative physical properties have been previously established by astronomical observations. Astronomers determine the luminosity, distance, size, mass, density, chemical composition, motion, and magnetic fields of these cosmic objects, while astrophysicists interpret and explain the astronomical observations using diverse aspects of physics, including dynamics, mechanics, statistical mechanics, continuum and line radiation processes, atomic and molecular physics, quantum mechanics, nuclear and particle physics, thermodynamics, and special and general relativity. Good astrophysics includes the prediction of definitive, new observational consequences. An example was the interpretation of pulsars, discovered by radio astronomers, as radio beams emitted from rotating neutron stars, with the prediction that the observed pulsar periods would lengthen as time goes on and the rotational energy of the neutron star is expended. Bad astrophysics includes mathematical speculations with sufficient adjustable parameters to accommodate most future observational tests. Recent developments in astrophysics include the explanation of the pervasive 3° microwave background as the relic radiation of the Big Bang; galaxy formation in the earliest stages of the expanding Universe; the interpretation of cosmic X-ray sources in terms of a neutron star or black hole that is accreting material from a nearby stellar companion; and the implications of unexpectedly high-speed motions at the peripheries of galaxies or within galaxy clusters in terms of invisible dark matter required to hold the visible moving material together. More speculative astrophysical concepts, which may not be stringently constrained by observations, include theories of the origin of the Big Bang, cosmic inflation, dark matter and dark energy, and string theory.

Self-identification

Science

Astrophysics self-identifies as a science that explains the observed physical properties of the

known physical constituents of the Universe outside the Earth. It assumes that these celestial bodies obey identical physical laws to those on Earth, such as the laws of universal gravitation, dynamics, and thermal radiation. Astrophysicists use these laws to describe celestial bodies, with explanations that can be tested and verified by decisive observations.

Religion

Astrophysics is not a religion, but it incorporates a belief in ordered physical behavior described by laws that operate throughout the observable Universe.

Characteristics

Astrophysics is a nonexperimental science in that celestial bodies cannot be taken apart or manipulated by controlled experiments in terrestrial laboratories, and astrophysical explanations of cosmic phenomena can only be verified by passive observations. Astrophysicists study matter in the Universe under extreme conditions of temperature, pressure, or density that cannot be achieved on Earth.

Relevance to Science and Religion

Astrophysics operates under a faith that objective physical laws, which are verified by experimental and observational tests on Earth, can explain physical objects throughout the Universe. Like religion, astrophysics often seeks a deeper understanding of phenomena that can operate beyond the range of known perception.

Sources of Authority

The ultimate source of authority in astrophysics is peer review by application of known physical laws, mathematical calculations, and verifiable predictions of observational consequences. Any astrophysical explanation of celestial phenomena must be tested through decisive, new

observations that show that the explanation is true or false, right or wrong.

Ethical Principles

Astrophysicists are skeptical, taught to question any discovery and to test it by repeated calculations and predictions of significant observations, and they are trained to employ personal detachment and uncompromising honesty. They focus on the predictable, repeatable aspects of the observable Universe, and their results are either verified or falsified through an ongoing process of peer review.

Key Values

The key value of astrophysics is the physical explanation of celestial bodies throughout the observable Universe.

Conceptualization

Nature/World

Astrophysicists regard nature as equivalent to the physical world outside Earth, although the natural terrestrial world is used as a foundation for physical laws thought to be applicable throughout the Universe. Nature is supposed to include both known and unknown cosmic objects and phenomena, either perceptible with contemporary astronomical telescopes or currently unseen and potentially observable with future instruments.

Human Being

Astrophysics does not normally consider either human beings or the pains and pleasures of human life. Such topics are thought to be outside the domain of astrophysical inquiry.

Life and Death

Astronomers and astrophysicists have shown that our planet and everything on it are composed of elements synthesized either in the nuclear crucibles of stars that exploded into space before the

Earth and Sun formed or before that, during the first moments of the Big Bang that gave rise to the expanding Universe. Despite our ability to pry living things apart, identifying their atomic, chemical, and molecular constituents, which can often be found outside Earth, no one has discovered the spark of life, showing how inanimate matter could have been transformed into a living thing, either on our planet or elsewhere. Astrophysicists forecast that life on Earth will not last forever, and that the entire human race is scheduled for extinction in a few billion years when the brightening Sun will vaporize the Earth's oceans.

Reality

To an astrophysicist, the real Universe consists of the currently observable one, but they often believe in a yet undiscovered, invisible reality that lies beyond the visible one and includes all that exists. Known celestial bodies, with well-defined, observed physical characteristics, are thought to be real, but so are other ill-defined celestial phenomena such as dark matter, dark energy, and supposedly empty space.

Knowledge

Astrophysicists regard knowledge of the Universe as a cumulative, ongoing process of the discovery and explanation of its ingredients and behavior.

Truth

Astrophysicists believe in an objective, scientific truth verifiable by decisive observations and significant tests. To them, truth in the extraterrestrial world consists of celestial bodies or phenomena that may be repeatedly and consistently observed and explained by known physical laws.

Perception

Astrophysicists provide possible explanations for the observations of astronomers who use new technology and novel telescopes to extend the capacity of their physical senses, thereby perceiving, becoming aware of, and eventually understanding otherwise invisible physical objects that lie outside the Earth and are inaccessible to direct observation. These perceptions are repeatable, and can be obtained by anyone using the same

or similar instruments. Some astrophysicists regard mathematical extrapolations of existing physical laws as a method of perception.

Time

Because light travels at a finite speed, astronomers look back into time when observing distant objects. As long as light passes through empty space, encountering no atoms or electrons, it can persist forever, bringing its message forward from the beginning of time to the end of the Universe. Powerful telescopes are therefore used as time machines to see objects as they were in the past, when their light was first emitted. They are seen as they were then and not as they might be now. The expanding Universe has a history, which astrophysicists decipher, but this only applies to times after the Big Bang about 14 billion years ago. No astrophysicist knows for certain what happened before the Big Bang, and time might have even begun with this creative event.

Consciousness

To an astrophysicist, consciousness is the mental awareness of the surrounding Universe, involving the perception of any physical object that might be explained by known physical laws.

Rationality/Reason

An astrophysical concept is rational if it uses accepted physical laws and can be decisively tested by significant observations. The use of mathematical equations in applications of physical laws to astrophysical situations may also be considered rational.

Mystery

The entire Universe is regarded as a great hidden mystery awaiting discovery and understanding, and its known constituents may also have mysterious aspects that remain to be examined and understood.

Relevant Themes

There are many critical, unexplained aspects of the Universe that lie outside the domain of

astrophysics, and are concerns of religion. They include the origin and fate of the Universe and life within it. No astrophysicist knows for certain what happened before the Big Bang, or how the observable Universe came into being, and they do not know if life originated from inanimate matter, or exactly what might have provided the spark of life on Earth. And owing to the recent discoveries of dark matter and dark energy, which we know almost nothing about, the eventual fate of the observable Universe remains unknown, despite the fact that distant galaxies are now accelerating into invisibility.

ATP

Stanley N. Salthe
Department of Biological Sciences, Binghamton
University, Binghamton, NY, USA

Adenosine triphosphate. The energy exchange medium in the biological cell. It is a chemical

that has three phosphate groups lined up in a row, the outer one of which is susceptible to being detached in such a way as to free up energy for use by the cell. The ATP can be regenerated from ADP (adenosine diphosphate) and Pi (inorganic phosphate) by an enzyme, using energy obtained from food in animals and from sunlight in plants, to reattach the third phosphate.

Normative Aspects of Attachment Theory

The term attachment refers to a strong disposition on the part of the offspring in many mammalian species to seek proximity to and contact with a specific figure and particularly to do so in certain situations such as when he or she is frightened, ill, or tired. John Bowlby, the founder of attachment theory (Bowlby 1969–1980), sought to understand this mammalian phenomenon by drawing mainly on principles from control systems theory and the theory of evolution by natural selection but also by incorporating selected principles from psychoanalysis (particularly the object relations theory and the independent school of British psychoanalysis), information processing theory, and the early literature on artificial intelligence. Bowlby argued that attachment behaviors have been naturally selected by mammalian species' ancestral environments (i.e., environments of evolutionary adaptedness, EEA) by keeping the offspring in physical proximity to their caregivers and thus protected from natural

dangers, such as predation. In other words, physical proximity is the predictable outcome (or set goal) of attachment behaviors, and increased chances of survival, in turn potentiating future reproductive success, is their evolutionary function. According to Bowlby, attachment behaviors are governed by an attachment behavioral system. This system is believed to be universal and to work similarly to mechanical systems, such as thermostats and goal-directed missiles, but to have been programmed by EAS rather than humans. Like other control systems, the attachment system is activated by certain conditions and deactivated by others. The attachment system is held to be activated by natural clues to danger, which can have both external (e.g., physical separation, predators approaching) and internal (e.g., fear, illness) sources. The system is held to be deactivated by natural clues to safety, most notably physical contact with the figure selected out as a source of security and safety (i.e., the Attachment Figure).

The attachment system is one among many evolved systems (e.g., exploration, reproduction, caregiving systems). Flexibility of functioning for the organism requires that these systems communicate rather than operate in isolation. For example, activation of the attachment system should be associated with deactivation of the exploratory system; when frightened by a sudden, loud sound, the offspring ceases to play (i.e., explore) and instead moves closer to the attachment figure (i.e., displays attachment behavior). The offspring's attachment system also operates in close synchrony with the caregiver's caregiving system, for example, when the former part is frightened and cries, (i.e., displays attachment behavior) the latter moves closer and picks him or her up (i.e., displays caregiving behaviors).

During the first year of life, the offspring typically develops one or a few attachment relationships, typically with their primary caregiver (s). Although the term "attachment" has broad connotations in everyday language, attachment relationships differ from other relationships (including close relationships in general) in important ways. Bowlby (1969–1980) and his

close collaborator Mary Ainsworth used the term “attachment relationship” to denote a strong affectional bond between two individuals, in which none is interchangeable with others. The attachment figure accomplishes two important functions for the attached person: (a) provides a safe haven in times of threat or stress and (b) serves as a secure base from which to explore the environment and develop new mental and physical skills. The attached person also resists separation from the attachment figure and experiences anxiety when involuntarily separated. Moreover, loss of the attachment figure leads to grief and mourning. Finally, the attachment figure is, at least implicitly, viewed as stronger and wiser by the attached person.

Bowlby (1969–1980) also argued that the offspring develops a set of partly unconscious mental representations, or internal working models (IWMs), of self and other, based on his or her interaction history with the attachment figure(s). These IWMs are held to reflect real experiences, to be continually updated based on new experiences, and to generalize to the individual’s representations of self and other in future relationships. Although IWMs are continually updated, principles of cognitive assimilation and behavioral automatization make a complete transformation of IWMs based on later experiences less likely. Therefore, Bowlby expected general continuity of IWMs across maturation and relationships while acknowledging that in the wake of radical and lingering shifts in experience, lawful discontinuity was to be expected. The partly unconscious nature of IWMs stems from the immaturity of the brain’s memory systems at early ages of development. In memory terms, early interactions with attachment figures are stored as implicit or procedural memories rather than as explicit or declarative memories.

Bowlby argued that psychological defenses are closely linked to peoples’ mental representations of self and other. In particular, he suggested that individuals who have consistently or often encountered insensitive caregiving will defensively come to exclude this information, for example, about parental rejection, from their

conscious experience and associated explicit/declarative memories. This, Bowlby believed, is especially likely if the caregiver provides inconsonant information to the child (e.g., “I love you so much”). In this example, the child is likely to develop an implicit/procedural representation of the self as unworthy of care and others as unlikely to provide care but an explicit/declarative representation of themselves as self-sufficient and others as loving. In other words, defensive exclusion was thought to lead to a structural incoherence (or multiplicity) of working models. Part of the strategy believed to underlie defensive exclusion is a defensive shift of attention, characterized by the individual attending to other aspects of the environment (e.g., toys) instead of, for example, a rejecting caregiver. Although Bowlby used information processing terminology, his usage of the term “defensive” (rather than merely “selective”) in reference of exclusion implied that a child who has received insensitive care uses a self-protective strategy to enable himself or herself to maintain behavioral organization vis-a-vis the caregiver and to ward off potentially overwhelming feelings of anxiety and anger. This account clearly connects Bowlby’s theory to the psychoanalytic idea of defense mechanisms. However, when the child’s needs for safety and security have been consistently met, according to Bowlby, the child will not need to resort to defensive strategies. In consequence, the IWMs of such individuals will display structural coherency (or singularity), where the child’s conscious/explicit feeling of worth will correspond with his or her actual (procedural/implicit) disposition to seek out care and advice when needed.

Individual Differences in Attachment Organization

Utilizing a semi-structured 20-min, 8-episode separation-reunion laboratory procedure for infants and toddlers, known as the strange situation procedure, Ainsworth and colleagues (1978) identified individual differences in child-caregiver attachment patterns (i.e., secure [B], insecure/avoidant [A], and insecure/resistant [C])

attachment). This procedure combines elements aiming at activation of both the child's attachment (i.e., novel environment, a participating stranger, separation from the attachment figure) and exploratory (i.e., novel attractive toys) systems. In this procedure, secure children strike a balance between attachment and exploration; they tend to use the attachment figure as a secure base for constructive exploration and protest separation, actively seek physical contact and/or interaction with the attachment figure on reunion, be comforted by the renewed contact with the attachment figure, and finally return to exploration. Avoidant children tend to engage in (defensive) exploration at the expense of attachment (i.e., a minimizing attachment strategy (Main 1991)); their exploration is marked by independence, they typically do not protest separation, and they do not seek physical contact or interaction with the attachment figure on reunion; indeed, they may even subtly avoid the attachment figure. Resistant children tend to engage in attachment at the expense of exploration (i.e., a maximizing attachment strategy (Main 1991)); they tend to cling to or be preoccupied with the attachment figure even prior to separation, protest separation strongly, and intermingle between passivity and angry resistance (e.g., temper tantrums) on reunion with the attachment figure, without returning to any constructive exploration. Mary Main and Judith Solomon (Main and Solomon 1990) subsequently identified a fourth category, known as insecure/disorganized/disoriented attachment, characterized by various behavioral breakdowns in attachment-related patterning in the presence of the attachment figure (e.g., prolonged freezing, marked anomalies or stereotypies, and sequential or simultaneous displays of opposing behaviors, such as moving away from parent while crying).

Empirical research has shown that aspects of caregiving tend to be the most robust and consistent predictors of attachment quality as assessed with the strange situation procedure, while the direct role (i.e., main effect) of genetic heritability has been found negligible in normal (twin) populations (Cassidy and Shaver 2008). More specifically, caregivers of children subsequently

classified as securely attached tend to be reliably sensitive to their child's signals (i.e., responding promptly and appropriately), caregivers of avoidant children tend to reject their child's attachment behaviors (e.g., show signs of discomfort with physical contact), caregivers of resistant children tend to be markedly inconsistently responsive (i.e., sometimes sensitive, oftentimes neglecting), and caregivers of disorganized children tend to be abusive and/or subtly frightening, dissociative, or frightened (Cassidy and Shaver 2008).

Individual differences in early attachment organization have been established as an important predictor of various aspects of socioemotional development in several long-term prospective longitudinal studies (Cassidy and Shaver 2008). For example, secure attachment has been found predictive of a high social competence and a low degree of behavioral problems throughout childhood and adolescence. In contrast, disorganized attachment has been established as an important attachment-related risk factor in development as it foreshadows later behavioral problems (e.g., aggression), dissociative inclinations, and psychopathology (Cassidy and Shaver 2008).

Attachment in Adulthood

Bowlby (1969–1980) emphasized that the attachment behavioral system is active “from the cradle to the grave,” and he suggested that long-term adult romantic or marital relationships are often the principal attachments in adulthood. Based on this notion, social and personality psychologists (Hazan and Shaver 1987; Mikulincer and Shaver 2007) began to study attachment-related aspects of adult relationships. Like Bowlby, these scholars suggested that the attachment, caregiving, and reproductive behavioral systems are integrated in long-term adult pair-bonds, for example, a given adult partner both gives and receives care within the pair-bond. In other words, unlike child-parent attachments, adult pair-bonds are symmetrical (i.e., none of the partners are consistently seen as stronger and wiser).

Based on the idea that adult pair-bonds involve attachment components, Cindy Hazan

and Phillip Shaver (1987) constructed a brief self-report questionnaire measure to assess adult attachment style, that is, an adult's typical perceptions, expectations, and behavioral inclinations in adult pair-bonds and other close adult relationships (see (Mikulincer and Shaver 2007) for methodological developments). Since then, attachment theory has established the position as one of the leading frameworks for understanding close relationships across the life span within many disciplines in psychology (most notably developmental, clinical, social, and personality psychology).

Religion as Attachment

Attachment theory has also made an important contribution to the psychology of religion (Kirkpatrick 2005; Granqvist and Kirkpatrick 2008; Granqvist et al. 2010). From the early 1990s onward, Lee Kirkpatrick has argued based on religious phenomenology and a review of 100 years of research and theorizing in the psychology of religion that believers' perceptions of God and their own relationship with God often tend to meet the established criteria for defining attachment relationships. In other words, God is viewed and used as an attachment figure, especially in theistic faith traditions characterized by the idea of a personal God with whom one may have a personal relationship. For example, regarding the proximity component of attachment, an important function of prayer is to establish a sense of connection or closeness to God. Also, people tend to turn to God as a safe haven when distressed. One example is that an overwhelming majority of sudden religious conversions occur during life situations of emotional turmoil. In addition, believers tend to describe God with words that are analogous to those used to describe other secure bases, for example, "loving," "guiding," "caring." Perceiving a personal relationship with a God thought to possess such secure base-related qualities has also been found, as expected, to confer certain psychological advantages (e.g., freedom from worry and guilt). Although religious teachings

maintain that God does not die or abandon people, the subjective feeling of losing a previously felt connection with God is associated with intense separation distress, a "wilderness experience," among believers. Indeed, according to much Christian theology, separation from God is the very essence of hell. Finally, God is thought to be omnipotent and omniscient, thus clearly stronger and wiser than believers themselves.

Novel empirical research on ► [religion as attachment](#) has corroborated Kirkpatrick's idea that people actually do use God as an attachment figure (Granqvist and Kirkpatrick 2008; Granqvist et al. 2010). For example, separation-related exposures (such as "God has abandoned me") have been found to increase theistic believers' motivation to experience closeness to God, even when delivered subliminally (i.e., unconsciously for the study participants). It should be noted, however, that unlike other attachment figures, God does not have a visible interaction history with believers. Partly therefore, it has been suggested that the believer-divine relationship should be considered an attachment-like relationship, or a symbolic attachment, rather than an attachment proper (Granqvist and Kirkpatrick 2008; Granqvist et al. 2010).

Kirkpatrick also proposed two hypotheses, the compensation and correspondence hypotheses, about how individual differences in attachment may relate to religiousness (see Kirkpatrick 2005). Since then, these hypotheses have been revised (Granqvist and Kirkpatrick 2008; Granqvist et al. 2010). In the current formulation of the compensation hypothesis, it is stated that religiosity in the case of insecure attachment develops from explicit/controlled distress regulation strategies, where God is used as a surrogate attachment-like figure. This hypothesis is founded in Bowlby's (1969–1980) and Ainsworth's discussions of the use of surrogate attachments among children whose principal attachment figures are or have been unavailable or unsatisfactory. In support of this hypothesis, empirical research has shown insecure attachment to be related to, for example, sudden religious conversions during life situations marked by emotional turmoil.

In the current formulation of the correspondence hypothesis, it is stated that religiosity in the case of

secure attachment develops from (a) generalized, positive representations of self and other (IWM aspect) and (b) partial adoption of a sensitive caregiver's religion (social aspect). This hypothesis is founded both in Bowlby's (1969–1980) idea of generalizing IWMs and the proposition that secure attachment facilitates successful socialization of parental values in general. Supporting this hypothesis, empirical research has found secure attachment to be related to, for example, a loving God image, the use of God as an available safe haven even at implicit/unconscious levels of operation (presumably due to a coherent/singular representation of God), and a high degree of parent-offspring similarity in religiousness.

Extant research on religion as attachment has used a wide variety of research methodologies. The published literature includes studies using different data collection methods (e.g., self-report questionnaires, semi-structured interviews, lexical decisions), research designs (cross-sectional, prospective, and experimental designs), religious populations (e.g., Swedish Lutherans, New Agers, Pentecostals, Americans from the "Bible Belt," Israeli Jews, Italian Catholics), and participants in different developmental periods (children, adolescents, young adults, elders).

[Concentration](#); [Focalization](#)

Description

“▶ [Attention](#)” is one of the major domains of psychological functions and, as such, it is central to our understanding of the mind. In the fields of

experimental psychology and cognitive science, attention typically refers to the set of functions that prioritize the processing of information relevant to immediate task goals. Occasionally, the term “attention” is also used to refer to nonselective functions relating to states of arousal, effort, concentration, or vigilance. Though these state-related functions may interact with selective attention functions, it is best to draw a clear conceptual distinction between them, and to reserve the technical term for selective attention functions.

The content of our conscious experience is highly selective: at any given moment, only a very small number of events will come to occupy our awareness, and consequently, drive voluntary behavior. These events are drawn from a boundless stream of continuous sensory stimulation by the mechanisms of selective attention, which enhance the processing of potentially relevant information while suppressing processing of irrelevant, and potentially distracting, sensory input. Selected information can then be used more efficiently to guide purposeful, or goal-directed, action. Selective attention has been most intensively investigated within perception. However, similar mechanisms for prioritizing behaviorally relevant information also operate within internalized representations of events maintained within short-term, or working memory. The selective retrieval of relevant long-term memories could also rely on mechanisms related to selective attention, but this is only beginning to be explored in the psychological literature.

Attention and conscious “awareness” are strongly interrelated concepts. One prevalent view is that awareness is the direct product of selective attention, insofar as only prioritized and selected events come to occupy awareness. Neurological case studies provide striking evidence that attention is a necessary precondition for perceptual awareness. “Hemispatial neglect” is a neurological syndrome characterized by a pathological failure to attend to sensory information from affected spatial locations, typically the side of space opposite to the site of damage. As a result of the spatial inattention, information at unattended spatial locations typically fails to reach conscious awareness. However, even

though few would dispute that attention is necessary for determining the contents of awareness, it may not be sufficient. In some cases, what drives our behavior may not conform fully to what occupies our awareness. It is possible, therefore, that some events may be prioritized and selected for guiding action without reaching conscious awareness. In the intriguing case of “► [blindsight](#),” individuals with damage to the primary visual cortex show some residual goal-directed action toward, and accurate “guessing” about, events that they do not experience phenomenologically. Moreover, selective attention can optimize behavioral responses toward events that are not consciously perceived by these patients. Therefore, although attention and awareness are tightly interrelated, they should not be considered to be synonymous.

The study of attention can trace its roots to the earliest days of experimental psychology and psychophysics. Herman von Helmholtz (1867) provided the first well-known empirical observations that it is possible to control the focus of spatial attention at will, independently of the location of the eye gaze. He built an apparatus in which it was possible to illuminate a display containing several letters for a fraction of a second. While holding his gaze at a fixed location, he noted that it was impossible to view simultaneously all the items in the briefly presented display. However, he found that he could reconstruct the display by mentally focusing on specific locations of the display, over multiple iterations, while continuing to hold his gaze fixed. After Helmholtz’s seminal empirical explorations into voluntary attentional control, William James (1890) lucidly described many of the principles and properties of selective attention. Using introspective methods, James wrote what was to become the most highly cited quotation defining selective attention:

Everyone knows what attention is. It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration, of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others, and is a condition which has a real opposite in the confused, dazed, scatterbrained state. . .

Attention in Early Cognitive Psychology: Capacity Limitations

After an extended hiatus during the behaviorist movement, when the study of internal mental processes, including attention, was discouraged, the study of attention once again took central stage within the emerging fields of cognitive psychology and neuropsychology. Psychological tasks, such as the dichotic-listening task, were developed to test the behavioral consequences of focusing attention on one out of multiple competing streams of information versus dividing attention among the multiple streams. The major aim of these early studies was to determine where the resource “capacity” for information processing became limited, that is, the stage at which simultaneous processing of multiple tasks becomes impossible. The empirical data gathered during these early days of cognitive psychology showed that it was possible to focus effectively on one stream of information based on basic physical characteristics of the signals (e.g., spatial location or pitch) so that little of the irrelevant, competing auditory stream reached awareness. However, occasionally, salient information from the irrelevant stream, such as the individual’s name, or information that was related to the attended message, was registered. Different scholars used such findings to support contrasting theories. “Early selection” theories, first proposed by Donald Broadbent (1958), placed the capacity limit, or “*bottleneck*,” at early stages of information processing. They held that information related to irrelevant sensory streams is filtered out, or attenuated, during the earliest stages of perceptual processing. “Late selection” theories, first proposed by J. Anthony Deutsch and Diana Deutsch (1963), placed the bottleneck much later during information processing. They contended that information processing was unimpeded until after semantic analysis of stimuli, after which only relevant information was selected to drive awareness or action.

Attention in Contemporary Cognitive Neuroscience: Selection and Integration

In more recent years, technological advances have paved the foundation of a new scientific perspective into attention. Cognitive

neuroscience exploits a range of powerful methods to measure and manipulate brain activity, thereby permitting systematic analysis of how activity in different neural structures and networks is modulated by task goals. To date, the majority of attention research has been carried out using visual spatial selective attention, where visual events at an instructed, or cued, location are made relevant to the task goals (e.g., covert orienting, Posner 1980). Nevertheless, studies have also shown that it is possible to orient attention to objects, features within objects, temporal intervals, and high-level associative attributes of stimuli. Moreover, similar mechanisms of selection also govern perceptual processing within other sensory modalities (e.g., audition, touch) as well as across modalities (e.g., between vision and audition).

Although our understanding of the neural mechanisms by which selective attention prioritizes and selects task-relevant events remains incomplete, important strides have been made. The evidence to date shows clearly that the biasing of information processing according to task goals is a widespread property across sensory, motor, and associative regions of the brain. The findings, therefore, argue against fixed points of limited capacity during information processing, but instead indicate that the mechanisms of selective attention operate at multiple stages. Emerging consensus is gathering around the theoretical view that the function of selective attention is to deliver the relevant data to guide perception and action within the current task goals and motivational state. This is achieved through two complementary mechanisms: “selecting” the attributes of the relevant events throughout multiple levels of the information processing stream, and integrating, or “binding,” the selected attributes into coherent objects.

Noninvasive recordings of brain activity from electrodes positioned on the scalp of human participants, using “*event-related potentials*” (ERPs), have indicated that the neural processing of a given event, such as a briefly presented visual stimulus, is strongly influenced by whether that event is potentially relevant to the current behavioral task. This type of recording based on the

electroencephalogram – event-related potential – has low spatial resolution, but it enables monitoring of stimulus-related brain activity on a millisecond-by-millisecond basis, providing sensitive measures of successive stages of information processing from perception to action. Multiple stages of attentional modulation can be observed, which become dissociable under different experimental conditions, from early stages of perceptual analysis to higher processing stages related to semantic analysis and decision-making processes. Corroborative and complementary evidence has come from the measurement of changes in blood flow that are coupled to neural activity with “positron-emission tomography” (PET) and “► [functional magnetic-resonance imaging](#)”. PET and fMRI measure local changes in blood flow that accompany brain activity. Unlike ERP, these neuroimaging methods have high spatial resolution, but the temporal resolution is relatively coarse. Such experiments generally demonstrate selective modulation of neural activity: stimuli that are the target of a behavioral response within the current task activate perceptual cortex more strongly than a physically identical, but behaviorally irrelevant stimulus. In the case of visual tasks, such attentional modulations have been observed across the hierarchy of visual areas, including in primary visual cortex, lateral geniculate nucleus of the thalamus, and superior colliculi. Direct recordings from individual neurons in nonhuman primates performing visual tasks have also confirmed modulation of neuronal activity across the visual hierarchy, including cortical and subcortical regions.

According to one of the prevailing contemporary theories of attention, selective attention “biases” neural competition in sensory areas via “bottom-up,” sensory-driven mechanisms favoring high-contrast events and by “► [top-down](#)” feedback signals, which carry information about the task goals (“biased competition” model: Desimone and Duncan 1995). During visual perception, for example, sensory input from the retina proceeds through a number of processing stages. This stimulus-driven input is integrated along the hierarchy of visual brain areas, so that neurons within higher-level processing regions

are sensitive to progressively more complex features, and/or feature combinations, presented within increasingly large proportions of the visual field (i.e., receptive field). As a result of this convergence, multiple features and objects within the receptive field compete for coding. Some features will compete more strongly than others, due to inherent differences in stimulus energy (e.g., brighter and bigger stimuli), and therefore, will be more likely to be selected for further perceptual processing. In addition to this “bottom-up” selection, top-down attentional control mechanisms also bias perceptual processing via feedback signals that convey information about the task goals. Top-down biasing is achieved through a combination of cellular mechanisms. When more than one stimulus comes to occupy the receptive field of a neuron in a visual cortical area, activity related to the attributes of irrelevant distracting stimuli is filtered away. The tonic baseline activity of neurons coding a potentially task-relevant location or an object shape is also elevated relative to activity in neurons coding irrelevant locations or shapes. The activity across neurons that code relevant spatial locations also becomes more tightly synchronized within high-frequency, gamma bands and less synchronized within low-frequency, alpha bands, which in turn increases the impact that the output of these neurons can exert further down the hierarchy. Critically, as selected attributes become more strongly represented, neural interactions will also bias competition in favor of other attributes of the same item aiding co-selection and integration.

The result of a biased competition during perceptual processing is sometimes referred to as a “saliency map,” which encodes the spatial location of a small number of potentially relevant targets. It is not yet completely understood how these cellular mechanisms come together to prioritize processing of relevant events, and additional aspects of the cellular mechanisms are likely to be unveiled. But, in broad terms, it is presumed that, by enhancing the signals from neurons coding the relevant locations or attributes, filtering out distracting activity from the output of these neurons, and by synchronizing the

high-impact activity of these relevant and filtered signals, it is possible to select only the attributes of the relevant objects, which then become integrated into cohesive objects to guide conscious perception and action. According to this view, attention plays a major role in solving the difficult “binding problem” posed by the way that perceptual systems are organized, by helping piece together the constituent features of putative target events. An early account proposing a role of attention in the integration of the features of task-relevant objects was proposed by Anne Treisman (Treisman and Gelade 1980, Feature Integration Theory), though in this case only spatial biases were considered to be necessary for correctly binding features of potential target objects.

The setting and monitoring of task goals is part of the psychological domain of “executive functions,” which are thought to involve activity in prefrontal regions of the brain. Once task goals are established, biasing of task-relevant information may be mediated through working memory or long-term memory representations. In the case of spatial attention, a large-scale frontal-parietal network of areas has been implicated in providing the top-down feedback signals to bias information processing along the perceptual hierarchy (Mesulam 1981). In particular, parietal, frontal, and subcortical areas that code the location of events to guide eye movements may also play a prominent role in guiding spatial attention, even in the absence of overt eye movements. The overlap between the control of spatial attention and of eye movements is supported by co-extensive patterns of activation for the two types of functions obtained using functional magnetic resonance imaging, by the sensitivity of neurons to both oculomotor and attention functions in the same brain regions; and by the measurable and spatially specific influence in visual cortical excitability upon stimulation of the frontal area implicated in eye-movement control (frontal eye fields). A strict interpretation of spatial attention as the consequence of planned eye movements, and later of planned actions more generally, is known as the “*premotor theory of attention*.”

Self-identification

Science

The study of attention as a psychological domain has consistently been approached from a scientific perspective. However, one inherent difficulty in investigating attention is that it is a process that operates upon internal mental states. As such, it cannot be observed directly, but can only be experienced by the subject of the mental state. This inherent subjectivity has, at times, been considered reason for excluding attention, and other internal mental phenomena, from scientific enquiry, especially during the *behaviorism* movement.

Although it is not possible to negate the ontological subjectivism of a mental process such as attention, it is possible to observe and quantify its effects upon overt behavior and upon neural activity. For example, the effects of attention on behavioral responses and neural activity can be measured by experimentally manipulating the predictability of task-relevant stimuli (Posner 1980). Using this approach, attention is typically operationalized behaviorally as the optimization of motor responses (e.g., faster reaction times or more accurate perceptual discrimination) to detect or discriminate a predicted, expected stimulus as compared to an unexpected stimulus. Alternatively, it is possible to manipulate the number and type of distracting stimuli in visual search tasks (Treisman and Gelade 1980). In this case, the time required for accurate behavioral performance is taken to indicate of the duration of the attentional mechanisms required to select and integrate the task-relevant target objects.

Characteristics

The process of attention – as the prioritization of task-relevant information – is relevant to most psychological functions. Though mainly investigated in the context of perception, the selection and integration of task-relevant information is also relevant for memory, emotional processing, language, and motor control. Whereas the specific mechanisms for biasing and optimizing

neural activity in different neural systems may differ in the details, attention can be viewed as a basic principle underlying the efficient functioning of neural and cognitive systems.

Since the early days of Experimental Psychology, attention has been recognized as a fundamental aspect of human perception and behavior, and its investigation has enjoyed a privileged position in the field. The study of attention spans various levels of organization. The mechanisms of attention have been investigated within single neurons in perceptual and associative brain areas, in retinotopic maps within brain areas, across neural circuits, and at the level of behavioral responses and conscious reports. In this way, attention might provide a crucial bridge to span multiple levels of analysis within the human cognitive and neurophysiological system.

Relevance to Science and Religion

The study of attention has not played a prominent role in issues at the interface of science and religion. As a fundamental organizing principle of human cognition, see above, attention is relevant for understanding many aspects of the human mind. As such, it will be of relevance to issues in religion that relate to the human mind, such as how the human mind creates and transmits religious discourse.

The basic concept of attention – prioritization of certain items over other to achieve goals – can also be extended to high-level concepts such as an individual's system of beliefs. In this regard, one may focus on religious beliefs or prioritize religious interpretations of events.

The ability to focus attention and to block out distraction is required by many religious and spiritual practices, such as meditation, whose goal is to heighten awareness, self-awareness, and self-knowledge.

Sources of Authority

The primary source of authority is the empirical data. Scientific models of attention are built

upon the interpretation of data that are recorded by experimentalists, and disseminated to the academy via peer-reviewed publications in specialist journals. In practice, authority also comes from academic institutions (Universities and research institutes), funding bodies, and specialist organizations or societies to which academics may belong, via membership fees (Cognitive Neuroscience Society) and/or peer election (Society for Neuroscience; Royal Society). Together, these organizations strongly influence the direction of research in attention and the acceptance of particular interpretations of data. Nevertheless, in the end, as an empirical science, the absolute source of authority must remain with the data. In the absence of scientific fraud, data cannot be challenged, only the subsequent interpretations.

Ethical Principles

The study of attention poses no particular ethical challenges. Research follows established ethical guidelines for experimentation on humans and animals.

Society can benefit in two different ways. The enquiry into attention enhances our understanding about the human mind and brain. Traditionally, beneficiaries have been largely limited to academics and university students; however, there is an increasing focus to educate the broader community via the public media. Findings from basic research can also fuel translational or clinical research, whose aim is to develop and evaluate treatments for disorders involving attention (e.g., attention-deficit hyperactivity disorder, neglect).

Key Values

Research into attention, as a major psychological domain, is part of the academic quest for knowledge about the biological mechanisms of cognitive systems, undertaken with scientific integrity and rigor.

Conceptualization

Nature/World

The study of attention does not conceptualize nature/world any differently from other empirical sciences.

Human Being

The majority of scientists engaged in the scientific study of human cognitive mechanisms, including attention, consider the human being as a species of primate that, although highly advanced, shares a continuity of cognitive complexity with other living creatures. In practice, researchers often emphasize the similarities, rather than differences, between humans and other primates, to the extent that there is little consensus as to whether humans possess any entirely unique cognitive faculties that cannot be observed in some form within other species.

Life and Death

The study of attention does not conceptualize life and death any differently from other biological sciences.

Reality

Cognitive psychology and neuroscience recognize that external reality is not fully and directly apprehensible through perception. Our senses transduce only a small fraction of the external energy impinging on the individual. Furthermore, our perception is guided by a complex interaction between the transduced external information (through vision, touch, audition, etc.) and internal signals (based on past experience, motivation, current goals, etc.). Our apprehension of reality is therefore highly subjective, and greatly determined by the process of selective attention.

Knowledge

The study of attention has little bearing on general concepts of knowledge. However, selective attention may play an important role in shaping an individual's corpus of knowledge, accumulated through his or her accumulated experiences (also referred to as semantic memory). The selective biasing of task-relevant or salient

information is thought not only to guide awareness and action, but also to guide the formation of memories, including memories for meanings and facts.

Truth

The study of attention does not imply any specific conceptualization of truth.

Perception

The study of attention is central to the understanding of perception, as already described in the main definition of this entry. In short, perceptual awareness may be considered as the result of attentional processes operating upon the competitive processing of signals triggered by the transduced sensory stimulation. Our perception is highly selective, limited to only a few items, and highly determined by subjective factors, such as our task goals and expectations.

Time

The study of attention has little to say about the nature of time. In contrast, it has revealed interesting insights about how our cognition unfolds over time, and about how we perceive temporal durations and intervals.

Our perceptual abilities have significant temporal limits. Studies in which participants are required to perform concurrently two or more tasks that require planning and production of separate responses reveal dramatic interference and performance costs, a phenomenon known as the "*psychological refractory period*." Even in the absence of speeded motor requirements, upon detecting a task-relevant event, people become unable to perceive another relevant event for hundreds of milliseconds, a phenomenon known as the "*attentional blink*."

The perception of temporal attributes – such as onset times, durations, and intervals – is also influenced by attention. Attended items are perceived to occur earlier than nonattended items ("*prior entry*"), and to last longer. Paying attention to the passage of time itself expands the duration of perceived time relative to paying attention to other aspects of an event.

Consciousness

Attention is strongly related to conscious awareness, as already explained in the main definition of this entry.

Rationality/Reason

The study of attention does not have any specific implication for the concepts of rationality or reason.

Mystery

The study of attention does not have any specific implication for the concept of mystery.

In social psychology, the term *attribution* has at least two meanings: the first refers to explanations of behavior (i.e., answers to why-questions) and the second refers to inferences or ascriptions (e.g., inferring traits from behavior, ascribing blame to a person). What the two meanings have in common, in science as in dictionary definitions, is a process of *assigning*: in attribution as explanation, a behavior is assigned to its cause; in attribution as inference, some attribute (e.g., a personality trait or blame) is assigned to the agent on the basis of the behavior. Despite the connection between these processes, they have distinct psychological characteristics and have evolved in two distinct historic lines of research. Both originate in work by Austrian philosopher and psychologist Fritz Heider (1958), who recognized attribution as a central process of forming subjective interpretations of the world, but the two lines emphasize different aspects of this fundamental insight.

Attribution as Explanation

Heider examined how people make sense of human behavior, and he argued that they search for causes of behavior. But people have two distinct conceptions of causality. They subsume purposeful human behaviors under a model of “personal causality” – according to which behavior is based on the agent’s intention, which is in

turn based on reasons. Quite different, the model of “impersonal causality” applies to any unintentional behavior and all other physical events; these events are brought about by causal forces that do not involve subjective reasons or intentions. Heider’s dichotomy is, in somewhat awkward terminology, the fundamental distinction between intentional and unintentional events – a distinction that arises early in infancy, is understood by other primates, and reaches a sophisticated conceptual structure in adulthood (Malle et al. 2001). Few concepts have as much influence on human social cognition as the folk concept of ► **intentionality**.

Surprisingly, however, attribution research soon moved away from Heider’s emphasis on intentionality. Whether it was an exegetic misunderstanding or perhaps a theoretically motivated simplification, attribution researchers after Heider claimed that people explain behavior by referring to one of two kinds of causes: either “person causes” (internal to the agent) or “situation causes” (external to the agent). This dichotomy is not the same as Heider’s personal/impersonal distinction, because, in the standard reading, “person causes” can be either beliefs, desires, and intentions that guide intentional action (e.g., She quit her job because *she felt the pay was too low*), or causal states that bring about unintentional behavior (e.g., He cried because *he was sad*). Likewise, “situation causes” can also guide intentional action (e.g., He chose Spain for vacation *because it is warm*) or bring about unintentional behavior (e.g., He fell because *the floor was slippery*). The person-situation dichotomy cuts across and, therefore leaves out the intentionality concept, implying that people care most about whether a behavior’s (main) cause is inside or outside the skin, not whether it was performed intentionally.

The most explicit theory of attribution that relied on this dichotomy (but relabeled it internal-external) was Harold Kelley’s covariation model (Kelley 1967). According to this model, people look for covariations between causes and effects, and they search for such information in service of finding out whether the behavior was internally caused (i.e., by the person) or

externally caused (i.e., by the situation). If Miriam experiences repeated headaches, she may look for triggering events that co-occur with the headaches until she finds whether something inside or outside of her appears to cause the headaches (e.g., a sinus infection vs. MSG in the food she eats at work).

The covariation model has limited applicability, however. First, it succeeds only when repeated co-occurrences can be observed. Second, the model delivers only whether the cause is “internal” or “external,” which by itself would be uninformative for most everyday explanations. Third, the model treats explanations of all events alike, ignoring the important distinction between intentional and unintentional behavior.

Empirical tests of the covariation model tended to support it, but only in experimental situations in which covariation information was explicitly presented. The few studies that have examined whether people actually seek out covariation information when answering a why question in everyday life have disconfirmed the model.

Doubts and criticisms of the standard attribution model had existed since the late 1970s, and even Heider himself, in an interview in 1976, argued that the literature had not adequately analyzed attributions of intentional actions to motives. It became clear that, when explaining intentional action, people don’t look for abstract things like internal vs. external causes or for covariation, but they try to construct the agent’s own *reasons* for acting (Malle 1999). Reasons are unlike any other causes. They are subjective states involved in a reasoning process that integrates what the actor desires and how she believes she can achieve it. Because social perceivers perform such belief-desire reasoning when they prepare to act themselves, finding another person’s reasons is not just pure observation; it is also perspective taking, reconstruction, and simulation of what one’s own reasons would be in the actor’s situation. The process of understanding why another person acted is, therefore aided by an act of imagination, but it is also constrained by the limits of such imagination – to most people, the serial killer’s

actions will remain a complete mystery, and even the actions of people from different cultures may feel not only unfamiliar but at times incomprehensible.

When people cannot imagine the agent's specific reasons or when they find those reasons unsatisfactory (e.g., "he wanted to kill people"), they often take a step back and look into the "causal history" of those reasons, citing factors such as personality, culture, and context that seemed to have contributed to those reasons (Malle 1999). The choice between reason explanations and causal history of reason explanations is guided by both cognitive processes (e.g., knowing or not knowing the reasons) and motivational processes (e.g., trying to portray the agent as rational and deliberate, which favors reasons) (Malle 2004). We see here the two major functions of explanations of intentional action: their cognitive function, which is to interpret behavior and provide meaning; and their social function, which is to manage ongoing interaction. These two functions hold for explanations of unintentional behavior as well, but those explanations are less central in social life, and they do not match the conceptual and linguistic richness contained in explanations of intentional behavior.

This more recent approach to attribution takes into account the folk-conceptual structure underlying behavior explanations – in particular, the intentionality concept and the notion of reasons – and by doing so, it resolves a number of inconsistencies in past research. For example, the famous hypothesis of an actor-observer asymmetry in attribution (suggesting that actors refer to more external causes than observers do) has been falsified by a recent meta-analysis of over 100 published research studies. But the hypothesis is falsified only when explanations are analyzed as internal vs. external; variants of an actor-observer hypothesis are strongly supported when explanations are analyzed in terms of their folk-conceptual structure. For example, due to both cognitive and motivational processes, actors offer more reason explanations for intentional behaviors than observers do (Malle et al. 2007).

Attribution as Inference

Beginning with Jones and Davis in 1965 (Jones and Davis 1965), researchers became interested in an inference people sometimes make when they observe another person's behavior: inferring the person's stable dispositions such as personality traits, attitudes, and values. For example, James sees Audrey putting coins in somebody else's parking meter and concludes she is kind. Jones and Davis's model identified two main conditions under which such dispositional attributions are likely: if the chosen action deviates from a norm and if it has unique effects when compared with alternative courses of action.

However, even when those conditions do not hold and situational demands instigate the behavior, people sometimes make dispositional attributions and are then said to display the "fundamental attribution error" (Ross 1977). This charge has become a core element of mainstream attribution work and generated several theoretical models to account both for the normal and the erroneous cases. In these two-stage models, an automatic trait inference in response to a behavior is followed by (often insufficient) correction for situational demands that are impinging on the behavior. The evidence supporting these models has been compelling, but, once more, no evidence outside of tight lab paradigms has been offered. There surely are cases in which a person is too quick to infer a disposition from another's behavior. But how frequent are such erroneous inferences in everyday life?

Traditional attribution work has portrayed social perceivers as always aiming at a dispositional inference – because, the argument goes, dispositions are predictive of future behavior. However, recent research suggests that social perceivers who interact and converse with each other in naturalistic settings are concerned less with prediction than with making sense of behavior in the here and now and with trying to grasp the meaning of other people's actions in terms of their beliefs, desires, intentions, and emotions. As a result, among the events people attend to in social interaction, dispositions make up less than 10%, whereas behaviors and ongoing mental

states make up 90%. And among explanations of behavior, no more than 5% refer to traits, whereas two thirds refer to mental states (Malle 2004). We must conclude that people are not dispositionists, as social psychology traditionally assumed, but mentalists. This observation converges well with developmental, evolutionary, and social neuroscience research, which considers the capacity to represent other people's mental states as the core of social cognition (Malle and Hodges 2005). It also converges well with recent research on the role of attributions in communication, which documents people's subtle responsiveness to the demands of an ongoing conversation and their focus on present actions and mental states.

Attribution and Moral Judgment

When a negative outcome occurs (e.g., a window was shattered), people try to find out who is responsible for the outcome and who is to blame. Such blame judgments often rely directly on causal attributions (e.g., whoever shattered the window is likely responsible) (Weiner 1995), but sometimes, they are more complex. When a window was shattered by the neighbor's dog trying to chase a cat, the dog owner may be responsible; if the window was damaged by a light wind, the builder who improperly installed the windows may be responsible. Responsibility and blame attributions are thus based both on assessments of causality (who brought about what) and on obligations (who ought to do or prevent what). In addition, attributions of responsibility and blame are critically dependent on the intentionality of the behavior in question. Obviously, a behavior is more blameworthy when it is judged to be intentional than when it is judged to be unintentional. But even among unintentional negative behaviors, those that are preventable are highly blameworthy because the agent *could have* formed an intention to prevent it. Such negligence is not as bad as intentional wrongdoing, but it is nonetheless blamable because humans expect each other to intentionally follow the norm of preventing harm.

The Search for Meaning in Human Behavior

Attribution research has played an important role in social psychology over the past 50 years. It has seen a theoretical evolution from simpler dichotomies to more complex, detailed models of how people conceptualize, cognitively process, and speak about human behavior. From the start, attribution work has highlighted the importance of studying social behavior by examining people's *perceptions* of behavior, as those often form the basis for social behavior itself. Likewise, it has illustrated people's persistent search for meaning in social interactions. The linking of behavior to its causes, especially the actor's reasons, makes meaningful what would otherwise be inexplicable bare movement.

People's search for meaning goes of course beyond social interaction and includes the attempt to understand the entire physical world. In these attempts, too, we can see traces of the folk-conceptual structures that are so prominent in explanations of behavior. When elementary particles have "charm," thermostats "notice" a temperature discrepancy, and evolution "selects" the fittest, we see the ease with which the human mind employs the familiar conceptual framework of mind and action. Likewise, most religious traditions ascribe to supreme beings the qualities of human agents, from desires to punish to plans and emotions, from perception and knowing to deliberate action. Gods, just as humans, are objects of attribution.

Related Terms

Autistic thinking

Autism is a *spectrum* condition, meaning that it is manifested to varying degrees of severity. At one extreme, a person may have no social skills, no language, and major learning difficulties. At the other extreme, the individual may have average or even above average IQ, precocious vocabulary (though a lack of interest in small-talk or chatting), and odd social skills (being one-sided or extremely self-centered). The former would receive a diagnosis of *classic autism*. The latter would receive a diagnosis of *Asperger Syndrome* (AS). Both of these are subgroups on the autistic spectrum. Both also share a strong preference for routines and repetition, and “obsessional” interest in highly specific topics.

The empathizing-systemizing (E-S) theory proposes that there are empathizing deficits in autism, while systemizing is either intact or superior. Empathy involves imagining another person’s thoughts and feelings, and having an appropriate emotional reaction to those feelings. Children and adults with AS show their empathizing deficits on age-appropriate tests of emotion recognition, theory of mind, and spontaneous empathy. Systemizing is the drive to analyze a system in terms of underlying rules in order to understand and predict its behavior. People with autism spectrum conditions show precocious understanding of systems, relative to their mental

Attributional Theory of Religion

Jakub Cigán

Department for the Study of Religions, Faculty of Arts, Masaryk University, Brno, Czech Republic

Derives from the general attributional theory in psychology and social psychology. It assumes human universal capacity of making sense of the world and creating plausible explanations of things, events, and persons. Attributional theory of religion focuses on situations and contexts,

age, on tests of intuitive physics or questionnaires assessing how interested a person is in different types of systems (maps, train timetables, machines, syntax, etc.). The unusually strong repetitive behavior, the strong desire for routines, and the “need for sameness,” can be seen as the result of a strong drive to systemize. Systemizing also requires excellent attention to detail, and people with autism and AS are faster on visual search tasks.

Anatomical abnormalities have been identified in different brain regions in autism. The brain regions that have been reported to be atypical include the cerebellum, corpus callosum hippocampus and the amygdala. Epilepsy also occurs in a proportion of individuals with autism spectrum conditions, though the exact rate is no longer clear. The number of Purkinje cells in the cerebellar cortex is abnormally low. Abnormalities have also been reported in the density of packing of neurons in the hippocampus, amygdala, and other parts of the limbic system. Abnormalities have also been found in the functioning of the amygdala, the orbito- and medial-frontal cortex. These atypical patterns of neural activity arise in relation to the empathizing deficits.

Today, we recognize that 1% of children have an autism spectrum condition. The sibling recurrence rate is 5–10%. Regarding twin studies, 60% of monozygotic (MZ) pairs are concordant for autism versus no dizygotic (DZ) pairs. When a broader phenotype is considered, 92% of MZ pairs are concordant as compared to 10% of DZ pairs. Molecular linkage genetic studies have led to a number of chromosomal regions being implicated, such as 2q, 7q, and 15q (Baron-Cohen 2008).

Description

Permanently searching for automation is an interdisciplinary area of study searching for applications of mechanics, control theory, and electronics to improve the quality of human life or enhance human tasks under different religious, social, economic, and political conditions. The word automation is a contraction for automatic operation, and the inspiring ideas can be traced back to 2,000 years ago (Bennett 1996). Automation is based on control theory and the concept of feedback (the output is compared permanently with the input to produce an error, and the goal

is to minimize the error between desired and actual). The area of automation first developed during the industrial revolution to control process variables such as temperature (boiler control for steam generation), pressure (pneumatic systems), liquid levels, and the speed of rotating machinery (steam engine governor). Later, electricity and electronics were incorporated for measurement, transmission, and manipulation of signals and for actuation (Bennett 1996). During the Second World War, automation brought together mechanical, electrical, and electronic engineers to solve complex problems, i.e., aiming of anti-aircraft guns, electric motor speed control, and ship and aircraft steering. By the end of the war, the classical control techniques have been established, and books published during the 1940s and early 1950s helped to disseminate results. Automation is pervasive in industries where there is a constant need for faster, efficient, and green manufacturing (Difrank 2008; Hitomi 1994).

In recent years, control theory and automation have incorporated mathematical models and techniques inspired by living systems, for example, artificial neural networks are simplified models of the nervous system; the genetic algorithm is an optimization technique that follows the principles of natural selection; artificial immune systems are basic models of the actual immune system; and electronic controllers such as the electronic gene and the emulated DNA chip model the working principles of gene expression and gene networks.

Self-Identification

Science

Automation is an interdisciplinary area of study and takes concepts from physics, chemistry, biology, and mathematics. Plant and process models are based on first principles; control strategies are formulated in mathematical language with rigorous proofs; recent control techniques known as computational intelligence or machine learning are inspired by natural systems.

Distinction Among Other Disciplines/Religions

Automation integrates mathematics, chemistry, biology, and physics around practical applications. Mathematical models are used to understand real-world problems and to design control strategies; computer simulations are used to reduce costs or to test the limits of the proposed physical systems.

Relevance to Science and Religion

There is no deep connection between automation and religion. While some religions may see work as punishment, automation improves labor conditions by freeing workers from tedious or dangerous activities.

A recent use of automation argues for a limit on physical labor by orthodox Jews during the Sabbath, a time for peace and relaxation during which any work or act of creation is prohibited. Jewish law prohibits manually turning on and off electrical devices, as this act is a demonstration of mastery. Automation might be described as an enhancer of religious experience since technology performs human activities and supports spiritual experience (Woodruff et al. 2007).

Sources of Authority

The source of authority for this discipline comes from first principles, mathematical theories, experiments, computer simulations, and successful technological implementations. Control theory provides the mathematical framework for automation.

Ethical Principles

The ethical principles are the same as in any human endeavor. There are moral questions about automation taking jobs from people or replacing humans with machines.

Key Values

The key values are to respect, value, and protect human life; improve the quality of human life by minimizing dirty, dull, and dangerous activities; respect nature; and follow environmental regulations.

Conceptualization

Nature/World

The natural world is to be mastered and controlled in a responsible, sustainable way to enhance human happiness.

Human Being

The main purpose of automation is to free humans from dull, dangerous, and dirty tasks by using mechanics, control theory, and electronics.

Reality

Automation is applied to reality to improve human living conditions.

Knowledge

Control theory is knowledge developed to support automation. New knowledge is created by modeling and simulating real-world situations.

Truth

Mathematical theories need to be proved and be true.

Perception

Measurements of variables to perform control loops.

Time

Time is fundamental for faster and more efficient processes. Automation happens in a real context.

Mystery

Reality is modeled, and experiments are designed to learn and reduce mysteries. Current models of reality are used to understand the world (Muller et al. 2001).

Autonomic Nervous System

Max J. Hilz

Department of Neurology, University
Erlangen-Nuremberg, Erlangen, Germany

Department of Neurology, Medicine and
Psychiatrie, New York University, New York,
NY, USA

Related Terms

[Autonomous](#); [Nervous system](#)

The autonomic (or vegetative) nervous system (ANS) is that part of the nervous system that is not under our direct volitional control, but assures permanent and instantaneous adjustment of body and organ functions to changing needs and conditions, e.g., at rest or during stress, when supine or standing, in warm or cold environment, during sleep, digestion, effort, intercourse, while walking or sitting, meditating or working mentally, etc. Thus, the ANS serves our bodily, emotional and behavioral functions by adapting the multitude of, e.g., cardiovascular, respiratory, thermoregulatory, metabolic, endocrine, gastrointestinal, urinary, reproductive, and other functions and responses to changes in the surrounding, external as well as in the internal milieu. These complex tasks involve central and peripheral parts of the ANS and integrate

behavioral and physiologic status and responses (Hamill and Shapiro 2004).

The term “autonomic nervous system” was first introduced in 1898 by the Cambridge physiologist John Newport Langley (November 2, 1852–November 5, 1925) who divided the ANS into the sympathetic, parasympathetic, and enteric (intestinal) systems (Langley 1921). Yet, there is also a complex central autonomic network involving areas in the spinal cord, brainstem, and brain that interact with each other, receive peripheral visceral and humoral afferences and modulate the peripheral ANS and visceral organs (Bennarroch 1997, 2004; Blessing 1997; Hilz 1999; Saper 2002).

The central ANS participates in the control of endocrine and somatosensory systems. Among the multiple and interconnected areas of central autonomic modulation are the insular cortex with influence on blood pressure, heart rate, respiration, gastrointestinal motility, secretion, saliva production, piloerection, pupillary dilatation (Bennarroch 2004; Hilz 1999; Saper 2002; Verberne and Owens 1998); the ventromedial prefrontal cortex, anterior cingulate gyrus; the amygdala modulating emotional and fear responses; the basal forebrain and limbic striatum, the hypothalamus, and the periaqueductal gray modulating motor, pain perception, and autonomic stress responses (Bennarroch 1997, 2004; Blessing 1997; Hilz 1999; Saper 2002).

The parabrachial nucleus participates in cardiovascular, respiratory, osmo- and thermoregulatory, and gastrointestinal activity including taste and saliva production (Bennarroch 2004).

The dorsal pons includes a “pontine micturition center” and innervates sexual organs, bladder and bowel, and pelvic floor muscles (Bennarroch 2004; Blessing 1997; Saper 2002). The nucleus tractus solitarii in the dorsomedial medulla oblongata is a most important relay area for visceral and taste afferents, and viscerosensory input to all areas of central autonomic control. It has areas for taste, gastrointestinal, respiratory, and cardiovascular afferents, and is involved in cardiopulmonary, gastrointestinal, baroreceptor- and chemoreceptor-reflexes (Bennarroch 2004; Blessing 1997; Saper 2002).

The ventrolateral medulla participates in vasomotor, cardiac, and respiratory control (Hilz 1999). The various areas of central autonomic modulation are interconnected at different levels (Hilz 1999).

The peripheral ANS can be divided into the sympathetic and parasympathetic systems (Hilz 1999).

Among the many responses mediated by the sympathetic system are increased melatonin synthesis, heat production in Brown adipose tissue, sweat secretion, pupillary dilatation, skin piloerection, light serous saliva production, increase in heart rate, excitability and contractility, bronchial relaxation, abdominal vasoconstriction, gastrointestinal motility decrease and sphincter contraction, increased bladder capacity and continence, male ejaculation and – depending on the type of receptors activated – variable changes in hormone secretion including insulin and glucagon from the pancreas, constriction or dilatation of small muscle arteries (arterioles), uterus relaxation or contraction, and catecholamine secretion in the adrenal medulla (Hamill and Shapiro 2004).

Preganglionic sympathetic nerve cells receive input from multiple supraspinal pathways, and arise from the intermediolateral and intermediomedial cell columns, at the spinal cord levels T1 to L2-3 (Hilz 1999). Using acetylcholine as main transmitter, preganglionic nerve fibers communicate via nicotinic synapses with the secondary or postganglionic nerve cells in paravertebral sympathetic chain ganglia, prevertebral, previsceral, or terminal ganglia. Among co-transmitters are substance P, neurotensin, somatostatin, enkephalins, GABA, serotonin, etc. The adrenal medulla is innervated by preganglionic fibers only, and produces mainly epinephrine (>80%), particularly during stress, and some norepinephrine (<20%) (Hamill and Shapiro 2004; Hilz 1999).

Postganglionic neurons innervate, e.g., blood vessels, pilomotor muscles, sweat glands, and internal organs via so-called varicosities that are packed with neurotransmitter vesicles mainly secreting norepinephrine (at muscarinic sweat glands acetylcholine); some neurons also use

dopamine, epinephrine, or serotonin transmission. Among co-transmitters are ATP, neuropeptide Y. Target organs have different adrenergic receptors such as α_1 -, α_2 -, β_1 -, β_2 -receptors (Hamill and Shapiro 2004; Hilz 1999).

The parasympathetic system mediates functions such as pupillary constriction, tear flow, serous saliva secretion, decrease in heart rate, cardiac excitability and contractility, increase in mucous bronchial secretion and bronchial contraction, gallbladder contraction, increase of gastrointestinal muscle tone, motility and secretion, gastrointestinal sphincter relaxation, pancreatic hormone secretion, voiding of the bladder, or penile erection.

Parasympathetic preganglionic neurons are located in the brainstem or sacral spinal cord, mainly at segments S2–S4. Long preganglionic nerve fibers synapse with short *postganglionic nerve fibers* in the “ganglia” (e.g., ciliary, submandibular, pterygopalatine, or otic ganglion), close to the target organs (Harati and Machkhas 1997).

Seventy-five percent of all parasympathetic activity is mediated by the *Vagus nerve* that travels from the brainstem to chest and abdominal organs, and the gastrointestinal tract to the level of the left colonic flexure.

Sacral preganglionic parasympathetic neurons from S2 to S4 receive spinal and supraspinal autonomic input, and mediate parasympathetic impulses via nicotinic cholinergic synapses to postganglionic neurons with short fibers and muscarinic, cholinergic neurotransmission to lower bowel and pelvic target organs. Apart from the neurotransmitter acetylcholine, there are various “co-transmitters” such as vasoactive intestinal polypeptide (VIP), nitric oxide (NO), calcitonin gene-related peptide (CGRP), galanin, peptide histidine methionine (PHM), and many others (Harati and Machkhas 1997).

The enteric nervous system contains 50–100 million motor, sensory, and interneurons and regulates bowel motility, secretion, and absorption. Largely independent from central control, three layers of interconnected ganglion cells, the plexus myentericus Auerbachii, the plexus submucosus externus Schabadaschii, and the

plexus submucosus internus Meissneri, coordinate peristalsis, and ion- and water-transportation across intestinal cells. Yet, there is also sympathetic and parasympathetic modulation of the enteric system. Among the abundant neurotransmitters and co-transmitters mediating motility activating or inhibiting signals are acetylcholine, substance P or norepinephrine, nitric oxide, and vasointestinal peptide (Hamill and Shapiro 2004; Hilz 1999).

Description

Awakening stands at the core of the Buddhist scheme of deliverance; hence, an understanding of its implications is of central relevance for a proper positioning of Buddhism in relation to the dialogue between science and religions.

The expression “awakening” renders the Sanskrit and Pāli term *bodhi*, sometimes also translated as “enlightenment.” This latter translation is less apt, however, given that the term *bodhi* derives from the verbal root *budh*, which means quite literally “to wake up” or “awaken.” An example for this usage can be found in a description of a person who sees various beautiful sights in a dream, all of which disappear as soon as he wakes up (Trenckner and Chalmers

1888–1896, I 365). The expression used to describe such waking up employs a derivative of the same root *budh*.

The term “enlightenment,” besides carrying unwarranted connotations as a referent to a European intellectual movement, runs the risk of giving the misleading impression that *bodhi* involves some form of a luminous experience. According to Buddhist meditation theory, however, visions of an inner light or luminosity rather pertain to the development of mental tranquility, which on its own is held to fall short of issuing in any of the levels of awakening recognized in Buddhism. Far from being an inner vision of light, awakening is better compared to the extinction of a light (Alsdorf and Norman 1966, Stanza 906). That is, what awakening refers to, in terms of actual experience, appears to be a cessation of the whole world as previously cognized and therewith inevitably also a cessation of any light or other visual object. In other words, what the Buddhist practitioner awakens to is the realization of Nirvāṇa.

The early Buddhist discourses, representing the earliest textual strata at our disposition for the study of Buddhist thought, indicate that with the realization of Nirvāṇa one awakens to a sphere of experience that goes beyond matter – represented in terms of the four main elements of earth, water, fire and wind – as well as beyond various forms of immaterial experiences (Steinthal 1885, 80). Nirvāṇa, as the unconditioned, stands apart from the conditioned nature of all other aspects of the world (► [Dependent Arising](#)).

The realization of Nirvāṇa is the goal of Buddhist soteriology, which stipulates as preconditions for such a realization a threefold training in morality, concentration, and wisdom. Morality in the sense of adherence to ethical conduct by abstaining from killing, stealing, sexual misconduct, falsehood, etc., is considered to provide the indispensable foundation for progress to awakening. Building on this foundation, an aspirant to awakening develops concentration as a basis for the growth of liberating wisdom, in line with the maxim that only a concentrated mind will be able to see and understand in such a way that genuine

wisdom arises. The arising of wisdom, from a Buddhist perspective, requires in particular insight into the three characteristics of conditioned existence. These three characteristics describe the nature of existence as being impermanent, as lacking any lasting satisfaction and as being devoid of an unchanging essence or self.

Central qualities required for the arising of liberating wisdom are the seven so-called factors of awakening: mindfulness, investigation of phenomena, energy, joy, tranquility, concentration, and equanimity. According to early Buddhist meditation theory, the bringing into being and maturation of these seven mental factors will enable the breakthrough to the actual experience of awakening.

Early Buddhist thought describes a breakthrough to awakening as taking place at four distinct levels:

- Stream-entry
- Once-return
- Non-return
- Arahantship

These four levels of awakening reflect the degree to which the mind has been liberated from ten types of fetters, mental forms of bondage that according to Buddhist thought are responsible for keeping the unawakened person bound to continued existence in the cycle of rebirths, *saṃsāra*.

On reaching the first of these four levels, the attainment of stream-entry, three of these fetters are eradicated. These are the fetter of personality view, which stands for belief in the existence of a permanent self (► [Anattā](#)); the fetter of doubt, in particular uncertainty regarding the nature of what is wholesome and unwholesome; and the fetter of clinging to rules and vows as in themselves sufficient for reaching awakening.

The actual experience of stream-entry involves the arising of the so-called eye of Dharma, a metaphorical description of the first “vision” – if it can be called such – of Nirvāṇa. Such direct realization of Nirvāṇa corresponds to insight into the four noble truths, in particular into the third of these four (► [Truths, Four Noble](#)).

The “stream” that has been fully “entered” at this point is the noble eightfold path

(Feer 1884–1898, V 347), which covers the central requirements for progress to full awakening (► [Truths, Four Noble](#)). The time required for this “stream” to lead the one who has entered it to the highest level of awakening, the full liberation of an arahant, is reckoned to be seven lives at most, none of which will take place in a lower sphere of rebirth.

The next two fetters to be overcome during progress to full awakening are sensual lust and ill will. A once-returner has made substantial progress in this respect, since with the second level of awakening these two fetters have been considerably weakened. Their complete overcoming is accomplished with the third level of awakening, the attainment of non-return.

An arahant has eliminated the remaining five fetters, which are desire for fine-material experiences, desire for immaterial experiences, pride, restlessness, and ignorance. With all fetters destroyed, it is held impossible for an arahant to be acting under the influence of desire, hatred, delusion, or fear (Carpenter and Rhys Davids 1890–1911, III 133). By dint of having fully awakened, an arahant is also said to be incapable of undertaking such deeds as deliberately depriving another living being of life, appropriating what belongs to others by way of theft, or consciously speaking falsehood (Trenckner and Chalmers 1888–1896, I 523). The inner aloofness reached with full awakening is also reckoned to make it impossible for an arahant to engage in sexual activity in any form, or else to hoard up things for the sake of sensual enjoyment.

With subsequent developments in later Buddhist traditions and the evolution of the bodhisattva ideal – the aspiration to become a Buddha in the distant future (► [Bodhisattva Ideal](#)) – the awakening of an arahant was seen as inferior to the awakening of a Pratyekabuddha (Pāli Paccekabuddha) – a Buddha who does not teach – and the awakening of a full-fledged Buddha.

The arahant, the Pratyekabuddha, and the Buddha already feature as distinct types of fully awakened beings in the early texts. While an arahant gains full awakening after having received the liberating teachings of a Buddha, a Pratyekabuddha and a Buddha reach the same without the guidance of a teacher. The two types

of Buddhas differ in as much as the Pratyekabuddha does not deliver teachings, whereas a Buddha is one who, having gained full awakening himself, teaches others the way to awakening. Thus, what in the early texts marks the difference between these three is mainly the way they reach awakening, whereas the notion that their actual awakening is substantially different appears to be a later development.

In sum, the Buddhist notion of awakening can be understood to refer to a distinct type of experience which, being based on the development of moral conduct and mental cultivation, in turn has clear ethical consequences. A fully awakened one is free from rebirth and any mental defilement, being incapable of breaches of morality. In other words, the experience of the unconditioned – Nirvāṇa – leads according to early Buddhist thought to an irreversible liberation of the mind, which has become totally awakened. According to a poetical comparison, the freedom of the fully awakened one is like a bird in the sky, which leaves no track behind (von Hinüber and Norman 1994, Stanza 93).

Basal Ganglia

Jörg-Peter Ewert
Faculty of Natural Sciences, University of
Kassel, Schauenburg, Germany

In the brains of tetrapod vertebrates, the basal ganglia refer to a group of interconnected subcortical nuclei: striatum, substantia nigra, globus pallidus (nucleus entopedunculus in anurans), and subthalamic nucleus. Neurotransmitters include dopamine, glutamate, and gamma-amino-butyric-acid. Participating in motor control, attention, and reinforcement learning, the basal ganglionic nuclei belong to the fundamental processing units of the tetrapod brain. Comparative studies of the anatomic connections, the chemoarchitecture and the development of the basal forebrain suggest that tetrapod vertebrates share a common pattern of basal ganglia organization.

Basic Programming Concepts

Linda Sherrell
Department of Computer Science,
The University of Memphis, Memphis,
TN, USA

Every computer program can be written using only three kinds of control structures: an assignment statement, a conditional, and a looping construct.

The basic assignment statement using the notation of the programming language Pascal is `<variable> := <value>` (e.g., `x := 7`); whereas in the programming language C or one of its derivatives, the assignment symbol is `=` (e.g., `x = 7`). The variable, which is a name for a location in memory, must appear on the left, whereas the value that will be stored at that memory location appears on the right. A purely functional programming language such as Haskell does not contain assignment statements; rather, the programmer uses functional composition (see terms in Mathematics), and the final value returned is the answer to the problem, which is specified as a conditional.

In many programming languages, the conditional is expressed as *if/else*, where the *else* part may be empty. This basic construct corresponds to the way that a programmer might express his

algorithm in natural language. In the declarative paradigm, which consists of functional (e.g., Haskell) and logical languages (e.g., Prolog), the programmer also specifies the problem as a conditional although the syntax differs. For example, in Haskell, the programmer may describe the problem with an empty list followed by a non-empty list; whereas, in Prolog, the programmer will specify the problem with a list of clauses that are executed until a clause becomes true. In each case, the *if/else* or *if/else if / else if . . . else* construct is inferred from the syntax.

Most imperative and object-oriented languages use a *while* to represent a loop. When a loop appears in the code, the computer checks a logical (Boolean) condition, and if true, the statements within the loop block execute in sequence, followed by a recheck of the Boolean condition at the top of the loop; otherwise, the loop terminates, and the next statement after the while executes. However, in a functional language, recursion (see below) replaces the looping construct.

Behavior Settings

Harry Heft

Department of Psychology, Denison University,
Granville, OH, USA

Extra-individual, dynamic ecological structures that are generated through the collective actions of individuals. These naturally occurring, emergent ecological structures are composed of both individuals' actions and the material features (affordances) that support them. Behavior settings are quasi-stable systems whose participants act to preserve setting integrity if circumstances threaten its stable functioning. By virtue of their participation in behavior settings, individuals' actions are constrained through their expression of the normative practices that characterize that setting. For this reason, behavior settings serve as reliable predictors of individuals' actions. The core concept in Roger Barker's ecological psychology.

Description

Behavioral medicine and health psychology are closely related fields of inquiry that were first recognized in the late 1970s. Behavioral Medicine, as defined by the Society of Behavioral Medicine (adapted from Schwartz and Weiss (1978)), is "the interdisciplinary field concerned with the development and integration of behavioral, psychosocial, and biomedical science knowledge and techniques relevant to the understanding of health and illness, and the application of this knowledge and these techniques to prevention, diagnosis, treatment and rehabilitation" (Society of Behavioral Medicine 2008). The standard definition of health psychology, provided by Matarazzo and adopted by Division 38 (Health Psychology) of the American Psychological Association, states that health psychology is, "the aggregate of the special educational, scientific, and professional contributions of the discipline of psychology to the promotion and maintenance of health, the prevention and treatment of illness, the identification of etiologic and diagnostic correlates of health, illness, and related dysfunction, and to the analysis and improvement of the health care system and health

policy formation” (Matarazzo 1982). Both are concerned with the relationships and reciprocal causal connections regarding how health/illness affects and is affected by biological, psychological, and behavioral factors. Consequently, both fields are oriented around the biopsychosocial model of health and illness. The classic definition of this model was provided by Engel (1977). “To provide a basis for understanding the determinants of disease and arriving at rational treatments and patterns of health care, a medical model must also take into account the patient, the social context in which he (sic) lives and the complementary system devised by society to deal with the disruptive effects of illness, that is, the physician role and the health care system. This requires a biopsychosocial model.”

The biopsychosocial model represents a ► [systems approach](#) to understanding health and illness. In this approach, the person is contextualized within an environment that consists of several levels (or analytic systems) including the physical, social, and cultural. The person must make continual adaptations to this environment. These adaptations involve the interplay of biological (at many levels, e.g., cellular, tissue, organ), psychological, and social factors. Important to this conceptualization are the following: (1) clear boundaries between levels/systems do not exist; (2) the dynamic interplay between systems is important for health/illness; (3) no level is logically superior to another but all are important and must be considered, in their interaction, to arrive at a comprehensive understanding of health/illness.

The primary distinction between behavioral medicine and health psychology is that health psychology is discipline specific whereas behavioral medicine is multidisciplinary. Therefore, only a psychologist could be rightly termed a health psychologist but any professional working in the areas described above could be a behavioral medicine specialist. Older conceptualizations of behavioral medicine as only involving behavior as applied to medical practice, namely treating illness, are now viewed as overly restrictive and no longer accepted. In what follows these two fields will be considered

simultaneously unless otherwise indicated. For simplicity the term “behavioral medicine” will be used.

Self-Identification

Science

Behavioral medicine has always identified itself as a science, albeit one that straddles the boundaries between the natural and social sciences and one that has strong basic and applied dimensions. It relies upon the findings from studies conducted using scientific methods to establish knowledge in the field, and basic as well as clinical research are carried out accordingly. Examples of these methods include case studies, single subject experimental designs, correlation studies, cross-sectional and longitudinal studies, and experimental and quasi-experimental studies that incorporate various controls. For treatment intervention studies the ► [randomized controlled trial](#) is considered the gold standard. Because of the types of interventions used in behavioral medicine, it is often not possible to conduct blinded studies. Specifically, double blind studies of treatment outcomes are nearly impossible to conduct and single blind treatment outcome studies are difficult, though sometimes possible. It is common to compare two active treatments and the use of attention-placebo controls, though present in some studies, is also sometimes deemed unethical or impractical. Similarly, it is not always possible, due to ethical or expense constraints, to use randomization and consequently non-randomized studies are also used.

Applied practitioners in behavioral medicine and health psychology typically practice out of a “► [scientist-practitioner](#)” model. In this model practitioners are trained in the methods of science so that they are at least minimally capable of reviewing, critiquing, and applying the scientific literature to their particular areas of practice. Nevertheless, it became clear that only a small minority of treatments actually had solid scientific support, a situation that led to calls for scientific examination of all treatments to determine their efficacy and effectiveness. In 2000 the

Office of Behavioral and Social Sciences at the US National Institutes of Health funded the first Evidence-Based Behavioral Medicine (EBBM) Committee and there is currently a strong movement in the field toward EBBM practice. The goal of this movement is to “enable practitioners to access effective techniques that can be used when their clinical expertise suggests that these will match the needs and preferences of individual clients” (Spring et al. 2005).

Characteristics

Behavioral medicine is distinctive in that it purposely and deliberately focuses examination on the relationships between physical aspects of health/illness and psychological/behavioral aspects of functioning. Consequently its domain is broad and extends beyond the boundaries of traditional disciplines to include areas of study relevant to fields such as medicine, public health, psychology, biology, chemistry, sociology, and economics. It is common, likely the norm, for research teams to be interdisciplinary in composition. As a result of these collaborations new fields have been identified. For example, a prototype of these new fields is psycho-neuro-immunology, an area of study investigating how and in what ways psychological responses to environmental input may influence immune system functioning and, ultimately, health outcomes. Health psychology shares with behavioral medicine the same topical areas for study and practice, thus establishing its distinctive quality among other areas of psychology. Strictly speaking, however, health psychology is not ipso facto an interdisciplinary field.

Relevance to Science and Religion

Behavioral medicine is interested in the scholarly discussion related to “Science and Religion” to the extent that this discussion has importance for understanding how religion or aspects of religious belief, practice, or experience influence and are influenced by health and illness as well

as behaviors, cognitions, and emotions related to health/illness. Thus religion (or aspects of it) may be viewed as either the independent or dependent variable in research studies. However, to this point religion is essentially considered as another psychological or behavioral variable among the many to be studied; one with no special status of its own. Further, from a theological perspective, the studies in behavioral medicine that do include religious variables tend to be unsophisticated in terms of their underlying theoretical foundation. Nevertheless, interest in the area of religion and health is increasing as evidenced by the formation of the Spirituality and Health Special Interest Group of the Society of Behavioral Medicine, increasing number of published peer-reviewed primary research articles, and the significant number of professional journals that have featured special issues on this topic. As noted by the title of the special interest group above, much of the attention to this area in behavioral medicine has recently become focused more on spirituality than religion per se. Discussions of a more fundamental nature concerning behavioral medicine and religion as related to epistemology, ontology, and methodology have largely not begun.

Sources of Authority

At the most basic level, the sources of authority in behavioral medicine are peer-reviewed primary empirical research publications found in scholarly journals in the field. These form the basis for secondary analyses such as meta-analytic examinations of particular questions or consideration by panels of experts who are convened by government and private agencies to issue statements regarding aspects of behavioral medicine (e.g., Is the Type A Behavior Pattern a risk factor for coronary heart disease?). Generally, recent journal publications carry more weight of authority than ones from the more distant past. Though it is technically the case that each reported study is judged on its merits, not the journal it is published in, it is nonetheless true that articles in journals with higher visibility tend to receive more citations both in print and at conference presentations

and are, therefore, more influential. It is also true that individual authors who have published many well-known studies tend to be viewed as authorities though, in keeping with the scientific spirit of the field, their authority is specific to their particular area of scientific expertise and their statements are always open to empirical challenge. There are many topical subareas, and their related journals, subsumed under the umbrella of behavioral medicine. Each subarea has its most visible journals and these constitute principal authorities for that subarea. Journals with broad coverage that often include influential articles on behavioral medicine include *Annals of Behavioral Medicine*, *Journal of Behavioral Medicine*, *Health Psychology*, *Psychology and Health*, *Journal of the American Medical Association*, *American Journal of Public Health*, *Journal of Psychosomatic Medicine*, and *the Lancet*, among many others. Professional presentations at the annual conventions of the Society of Behavioral Medicine, American Psychological Association, American Psychosomatic Society, and European Health Psychology Society are also potential sources of influence. In all cases, though, ultimate authority rests on the quality of the scientific findings pertaining to any question.

Ethical Principles

Behavioral medicine is guided by the ethical principles of the many disciplines that make up the field. Health psychology is governed by the Ethical Principles of Psychologists and Code of Conduct of the American Psychological Association (2002). Other influential writings include the AMA Code of Medical Ethics (American Medical Association 2008), the Declaration of Helsinki (World Medical Association 2008), and the Belmont Report (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1979). The most basic ethical obligation is to do no harm to patients and participants in research. Other core principles include fidelity and responsibility, integrity, justice, and respect for people's rights and dignity.

Key Values

The primary value of behavioral medicine is to prevent or ameliorate human suffering by the judicious application of knowledge regarding psychological and behavioral functioning in ways that are efficacious. A second value is the acquisition and distribution of knowledge regarding how human psychological and behavioral functioning influences and is influenced by health and illness.

Conceptualization

Nature/World

Nature is composed of the observable, or potentially observable, physical entities of earth and includes their dynamic interaction and attendant processes. Strictly speaking, world would be everything included on earth but in practice both nature and world could be expanded to include all observable entities and their interactions and processes in the universe.

Human Being

Human beings are biological creatures capable of self-reflection, advanced cognitive functioning, speech, abstract thinking, and creativity. Humans are typically social and capable of engaging in scientific and artistic pursuits. Humans appear to be unique in their universal proclivity to make moral and ethical judgments. Additionally, humans often report experiencing a spiritual dimension to their existence and the effects of this spiritual dimension are potentially the object of scientific study.

Life and Death

Humans are alive, or have life, when they are capable of carrying out physical and biological functions typical of their species. Behavioral medicine has not generally examined life apart from human existence, though the same definition used with humans would likely apply to other species. Behavioral medicine has not formally agreed upon statements on the origins of life (either for the individual or for the species). Death is viewed as the cessation of physical functioning.

Reality

There is a general common-sense notion in behavioral medicine that reality is the physical world surrounding humans. However, behavioral medicine is also interested in the “personal reality” of the individual, i.e., how the individual perceives his/her world and experience. It is thus recognized that reality, in the second sense, for any two people residing in the same environment may be quite different. Reality may be known, at least in part, through the methods of science.

Knowledge

Knowledge is that which is understood to be congruent with reality. Consequently, there is an objective knowledge that exists, i.e., proper understanding of the physical world and its functioning that is publicly verifiable, and a subjective knowledge, i.e., that which is understood by the individual and is in accord with his/her reality but may, at times, conflict with the subjective knowledge understood by others.

Truth

To the extent that truth is defined in behavioral medicine it is done so implicitly. Thus, in the search for knowledge behavioral medicine practitioners are engaged in an attempt to understand the true nature of things, i.e., the truth. However, behavioral medicine has not explicitly defined truth, likely because this construct is viewed as the purview of religion or philosophy.

Perception

Perception is a person's understanding of the meaning of a sensation. A sensation occurs when a sensory stimulus elicits a response from the sensory system that reaches the level of consciousness. In behavioral medicine perception is differentiated from sensation in that perception is a higher order mental process involving interpretive activity. This is most often salient in areas of behavioral medicine involved in studying pain.

Time

Time has to do with the ongoing relationships of objects to each other. Time is measured

objectively based on observations of changes in the relationships of objects in the surrounding environment. The subjective experience of time is freed from objective measures of relationships and thus time may be experienced as either speeded up or slowed down. This subjective experience is influenced by psychological states and physical occurrences.

Consciousness

Consciousness is the quality of being aware. Thus, one is conscious (and therefore experiencing consciousness) to the degree that one is aware of feelings, thoughts, perceptions, ideas, sensations, and reasoning. States of consciousness have to do with the degree that one is awake and alert and range from completely unconscious to being fully alert.

Rationality/Reason

Rationality has to do with the ability to think in ways that are in accord with the functioning of the physical world, the known facts, and the rules of logic. The more one's thought processes are congruent with these, the more rational one is thinking.

Mystery

Mystery, to the extent behavioral medicine has a position on it, would simply be that which is unknown. Behavioral medicine has not, however, specifically defined this term.

Relevant Themes

One other issue of some importance from the perspective of behavioral medicine regarding the Science and Religion interface deals with basic presuppositions regarding the nature of humans. For example, behavioral medicine is often concerned with issues of motivation and behavior change. Fundamental to these considerations are hypotheses regarding what motivates people to behave in certain ways and these hypotheses are, in turn, derived from underlying, bedrock, theories regarding the essential nature of humans. At this level there is, what has been to

this point, implicit or even unrecognized overlap between the “science” of behavioral medicine and religious doctrines. A more thorough and explicit discussion at this level of conceptualization about how behavioral medicine theories of motivation and behavior change relate to religiously based conceptions of human nature would serve to engage these disciplines in a significant manner.

Biases and Heuristics

Jason S. Nomi, Anthony J. Ryals and
Anne M. Cleary
Department of Psychology, Colorado State
University, Fort Collins, CO, USA

Biases are tendencies toward certain types of behaviors; the *confirmation bias* is the tendency to selectively notice information that confirms

what one already believes. *Heuristics* are simplified algorithms (i.e., “quick rules of thumb”) that people may use in the place of more complicated algorithmic rules in order to make a decision more quickly; the *availability heuristic* is the tendency to base judgments of likelihood on how easily an example can be retrieved from memory.

Bible

► Ecclesiology

Bible as Literature

Steven Marx
California Polytechnic State University,
San Luis Obispo, CA, USA

Description

“The Bible as Literature” denotes an academic subject taught in high schools, colleges, and universities and the academic specialty of a worldwide network of scholars. As a Library of Congress subject category in *World Cat* it elicits entries for 1,252 books. In recent years, practitioners have preferred the term, “Literary Study of the Bible,” which produces listings as the subject of 653 books. There is no professional organization or journal specifically devoted to the topic.

The Bible as Literature/Literary Study of the Bible is a subdiscipline of both Biblical Studies and Literary Criticism. Its activity is “exegesis,” i.e., commentary on and interpretation of the Bible.

The word “Bible” has several meanings. It refers to a collection of separate books and to that collection defined as a single book. The Jewish Bible consists only of the Hebrew Scriptures or Tanakh. The Christian Bible includes the books of the New Testament plus the Hebrew

Scriptures, which it refers to as the Old Testament. The Catholic Bible contains, in addition, the Apocrypha, a set of books not included in the Protestant Bible.

Literature is defined as “...artistic writings worthy of being remembered. ...that are characterized by beauty of expression and form and by universality of intellectual and emotional appeal” (Dictionary.com). Literary Study is defined as “the humanistic study of literature” ([WordNet®](http://WordNet.com)). “The purpose of a literary inquiry is a better understanding of the text – its construction, its forms of expression, its meaning and significance, and/or its relation to non-textual elements or to other texts” (Berlin 2008). Although the text that Literary Study examines is usually concrete and specific, no understanding it produces is exhaustive or conclusive.

The Bible as Literature/Literary Study of the Bible is governed by a set of ► [hermeneutic](#) methods – i.e., certain principles of commentary and interpretation. It takes a secular approach, treating biblical texts as works produced by human beings within human history rather than a theological approach, which treats them as Holy Scripture, Divine Revelation, or The Word of God. It applies techniques of literary criticism to the Bible in the same ways they have been applied to other literary works since the time of Aristotle. These include:

- Analysis of plot and structure
- Discussion of character, including the characters of narrator and author
- Exploration of theme
- Consideration of historical and geographic setting
- Delineation of linguistic and stylistic devices, including figures of speech and verse and prose conventions
- Categorization of genres
- Correlation of intertextual references to other works

Some readers within faith communities that adhere to a theological approach to biblical interpretation regard The Literary Study of the Bible as subversive; others see it as complementary.

The Bible as Literature/Literary Study of the Bible is also defined by contrast to a different

secular approach to the Bible known as the “Higher Criticism,” Textual Criticism, “Literarkritik,” or, confusingly, “Literary Criticism of the Bible.” This academic discipline studies the Bible as a documentary artifact, employing scientific methods to understand the historical or “diachronic” process that produced the texts accreted and deleted during the period in antiquity encompassing the Bible’s composition and canonization. While Higher Criticism attempts to reverse engineer the received text into earlier constituent layers and fragments, The Bible as Literature/Literary Study of the Bible interprets the received text as a completed “synchronic” whole at the end of its evolutionary history. It discusses characters and plot events in the present tense.

The Bible as Literature/Literary Study of the Bible emerged as a self-conscious academic specialty in the 1970s, but recorded interpretations are as old as the text itself. Examples of internal exegesis include Moses’ explanations of the purpose of the Sabbath day by reference to the seventh day of the creation, or Jesus’ interpretation of the laws of the Decalogue in his Sermon on the Mount, or St. Paul’s disquisitions on the spiritual rather than the literal meaning of circumcision portrayed in Genesis.

Early exegetes like Philo of Alexandria supplied allegorical interpretations of anthropomorphic features of the Hebrew God to make the Biblical deity palatable to rationalistic Hellenistic readers. During the Rabbinical period collections of oral interpretive commentary on passages of the Hebrew Bible were collected in the Midrash. Some Jewish and Christian commentaries, for instance, by Longinus and St. Augustine, acknowledged the richness of poetic and rhetorical language in Biblical passages of poetry or parable.

Medieval Jewish scholars described principles of parallelism in Hebrew poetry and patterns of metaphor, hyperbole, wordplay, and rhyme as well as different authorships of different sections of Isaiah. The Venerable Bede (672–735) wrote a treatise entitled *On Figures and Tropes of Holy Writ*. During in the Middle Ages the Bible also served as a model for original literary

writings like Dante’s *Divine Comedy* and English miracle and mystery plays.

The revival of classics and the rise of humanism and science during the Renaissance and Reformation generated more interest in the Bible as Literature. Petrarch, one of the modern originators of the idea of literature as an independent subject, stated that “the bible not only contains poetry, it is poetry at its core” (Wall 1995). In his “Defense of Poesie” from Puritan attacks against secular literature, Sir Philip Sidney celebrated the literary accomplishments of “David in his Psalms; Solomon in his Song of Songs, in his Ecclesiastes, and Proverbs, Moses and Deborah in their hymns; and the writer of Job” (Duncan-Jones and van Dorsten 1973). George Herbert admired the structural configurations of the text: “Seeing not only how each verse doth shine,/But all the constellations of the storie./This verse marks that, and both do make a motion/Unto a third, that ten leaves off doth lie. . .”(Herbert 1857) and John Donne expostulated upon the arcane beauty of its rhetoric: “thou art a figurative, a metaphorical God too; a God in whose words there is such a height of figures, such voyages, such peregrinations to fetch remote and precious metaphors. . .such things in thy words, as all profane authors seem of the seed of the serpent that creeps, thou art the Dove that flies” (Donne 1975). Works like Milton’s *Paradise Lost* and *Samson Agonistes* amplified such appreciation by using Biblical texts as sources for original literary production.

This development of literary appreciation of the Bible was accompanied by the beginnings of a scientific-historical approach. Lorenzo Valla applied meticulous scholarship dependent upon knowledge of ancient languages to finding, comparing, emending multiple manuscripts, leading the way to Erasmus’ critical editions of the Greek New Testament and Tyndale’s translation of the Old. Such scholarly efforts continued during the late seventeenth and eighteenth century Enlightenment. Spurred by the strategy of systematic doubt and reliance on reason and empirical observation developed by Bacon and Descartes, Spinoza declared that the Bible needed to be understood only on the basis of evidence present

within it and available to any reader. Reading unencumbered by theological presuppositions led to the first formulation of multiple authorship of the five books of Moses by Richard Simon in 1678.

This secular historicizing scientific approach was paralleled by further exploration of the aesthetic literary values of the Bible. Robert Lowth discovered that the principle of Hebrew poetics lay not in meter or rhyme but in the balance of ideas and phrases, which he discerned in the Psalms, the Prophets, and elsewhere. Lowth's literary-critical work inspired the poetry of Ossian and of William Blake, who based his idiosyncratic poetic and artistic output directly on Biblical models of style. Blake claimed that the Old and the New Testament were "the great Code of Art," that all great art is as visionary as the Bible, that poets are by definition prophets, and that all gods reside in the human breast.

These dual tendencies in secular Biblical exegesis continued throughout the nineteenth century. Scientific-historical analysis became known as "higher criticism," elaborated in the Documentary Hypothesis proposed by Julius Wellhausen. Based on linguistic and stylistic analysis of the Hebrew Bible texts, he postulated four strains – J, E, P, and D – written at different times in different political and cultural contexts, eventually knitted together by ancient editors known as redactors. This hypothesis continues to guide "Biblical Literature" studies today, where refinements and revisions still proliferate based on new discoveries and interpretations of material artifacts. Scientific/historical research proceeded in New Testament studies with efforts to separate myth and legend from fact in Gospel accounts of the life of Jesus, e.g., in David Friedrich Strauss's 1846 *Life of Jesus Critically Examined*, and in Adolph Harnack's, *What is Christianity?*, which placed New Testament stories and teachings in the context of Near Eastern religious traditions.

The Higher Criticism combined with the geological discoveries of Charles Lyell and the biological theories of Darwin to present direct challenges to religious worldviews based on

theological readings of the Bible and led to widespread Victorian soul-searching about the conflict between science and religion. An alternate approach, sidestepping that conflict was provided by the Bible as Literature movement, which, though secular, repudiated the Higher Criticism's atomism, reductionism, technicality, and insensitivity to the Bible's aesthetic values. One of its founders, Matthew Arnold, had abandoned belief in a personal God, but argued that the arts provided a worthy successor to religious faith, and as a superlative example of literature the Bible should remain as a central object of study and appreciation. Arnold maintained that the Bible's literary language was of a different order than the language of objective description subjected to scientific confirmation or rebuttal.

Following Arnold, "The Bible as Literature" became a popular phrase denoting the subject of academic research and college and high school English courses. By the middle of the twentieth century, T. S. Eliot and C. S. Lewis, prominent British author/critics who remained religious believers, objected to its secular subversion of the Bible's unique theological authority. The technique of intense close readings of biblical texts fostered by the "New Criticism" generated widely cited critical accomplishments beginning with the translation of Eric Auerbach's essay "Odysseus' Scar." It contrasted the Bible's spare characterizations and descriptions with those of the classics, finding them richer with suggestive depth and hidden complexity – "fraught with background" (Auerbach 1953).

Northrop Frye and Robert Alter, two literary critics and professors of English, made major contributions to the field during the latter half of the twentieth century. Though often in stark disagreement, both applied systematic theories of literary analysis which rewarded intensive attention with the discovery of subtle details and rich patterns of coherence. Frye's *Anatomy of Criticism* postulated an overall unity of language, plot, imagery, theme, and character, an analytical framework that he completed elaborating in his last three books, all of them about the Protestant Bible (Frye 1957, 1982, 1990). Robert Alter's *The Art of Biblical Narrative* developed

a technique for linking small and large units of composition in the Hebrew Bible through internal reference or allusion (Alter 1981, 1985, 1987, 1992). Their approaches have been classified as variations of “structuralism” or “narratology,” each claiming some scientific authority derived from methodological sources in linguistics and anthropology. These approaches also have more traditional roots: Alter’s in the rabbinical techniques of midrash (the collection of early Rabbinic commentaries on the Hebrew Bible, in general, a commentary on a text that is free and sometimes fanciful), and Frye’s in patristic typology and in the poetics of visionary experience he found in William Blake. Though secular rather than theological interpreters, Alter and Frye assume that the received texts are coherent and complete.

By the middle 1970s the abundant fruits of such formalist literary study of the Bible were attracting historical scholars and led to the launch of a new journal by their professional association, The Society of Biblical Literature. Titled *Semeia*, it combined historical with literary approaches to interpretation. At the same time some literary scholars adapted the historians’ idea of separate strains of biblical authorship to arrive at new literary readings. In the J strain, Harold Bloom found a complete literary masterpiece he ascribed to a woman at King Solomon’s court (Bloom and Rosenberg 1990). Leslie Brisman construed a dramatic dialogue in Genesis between the normative voice of Isaac, associated with the P strain, and the quirky voice of Jacob, associated with J (Brisman 1990).

The contrast between Literary Study of the Bible and other interpretive approaches has been further blurred by literary critics’ adoption of the “hermeneutics of suspicion” associated with the movement called post-structuralism, postmodernism, or Critical Theory. Rather than discovering formal coherence, aesthetic value, and truth of representation in the Bible, the new analytic methods have brought forth Feminist gender analysis, Marxist class analysis, New Historicist power analysis, Cultural Studies anthropological analysis, and Psychoanalytic depth psychology analysis. This expansion of

the category “Bible as Literature” has further stimulated research, publication, the organization of conferences, and the creation of courses. Some interpretations generated by these methodologies are offered as more scientific than traditional literary exegesis, some simply as “a reading,” one among many that are possible.

Such relativism regarding knowledge of the Biblical text has issued in two related avenues of inquiry in Literary Study of the Bible: (1) the history of interpretation, which determines Biblical meaning as the changing outcome of the way it is understood by readers in specified historical and ideological contexts and (2) intertextual studies, or “The Bible *and* Literature,” which explores how literary texts by later writers like Milton, Blake, Shakespeare, or Toni Morrison, interpret and are influenced by the Bible.

Recently developed “ecoliterary” and “ecocritical” approaches incorporate the biological sciences into the Literary Study of the Bible. They focus on Biblical representations of nature and of human and divine relationships with nature, particularly in light of present day environmental issues. Lynn White’s 1967 essay, “The Historical Roots of Our Ecological Crisis” (White 1967), asserted that a significant cause of that crisis is the influence of the Bible’s language commanding humans to “fill the earth and subdue it and have dominion over. . .every living thing. . .” (Genesis 1.27) This language has been reinterpreted to enlist the Bible in the cause of environmental stewardship, both by secular critics and by theological writers concerned with Creation Care or Creation Theology. In one of several hortatory introductory essays to *The Green Bible*, an edition that replaces red lettering for the words of Jesus with green lettering for words dealing with nature, Ellen Bernstein writes: “The ecological language of the creation accounts helps us discern the ecological vision alive throughout the Hebrew Bible. So we begin with a literary reading of these texts to see what we can learn about God and Gods relation to the world, and about nature and human nature” (Maudlin and Baer 2008). Such ecocritical biblical exegesis is practiced by fundamentalist, anti-Darwinian “creationist”

theologians (<http://www.icr.org>), by literary critics who find in Genesis evidence for an emerging ethos of anti-anthropocentrism (Walker-Jones 2008), by cultural geographers (Hiebert 1996, 2008), and by environmental scientists who study human history within the framework of natural history (Hillel 2006).

Another ecocritical approach is pursued in Agrarian Studies, which finds throughout the Bible an underlying theme of respect for the land, concern for soil, and appreciation for sustainable agriculture. Blending theology with science and literary analysis, Agrarian Studies supports efforts to reform the present industrial food system, to critique some applications of science in modern technology, and to revive local agriculture and the culture of farming (Davis 2009). The interplay between the Bible and such agrarian issues is prominent in recent ecoliterary works, including the writings of Wendell Berry, Barbara Kingsolver's novel, *Prodigal Summer*, and Ruth Ozeki's novel *All Over Creation*.

Yet another new ecocritical approach labeled "Darwinian Literary Studies" applies findings and methods of sociobiology, evolutionary psychology, and Darwinian anthropology to the study of literature. Assuming that natural selection "shaped the human mind, and thus human behavior, and thus human culture," it uses the mechanisms of evolution to make sense of literary activity and of the content of texts, claiming to find in them elements of a biologically determined and scientifically defined universal human nature. Such findings are "tied into a web of mutually reinforcing, falsifiable hypotheses in the biological and social sciences" and form part of the larger "tree of knowledge" uniting all of the sciences. According to Jonathan Gottschall, "Darwinian literary criticism . . . focuses on the fascinating multiplicity of ways characters . . . accomplish the prime directive of all life: to live long enough to reproduce and, in species where parental care is necessary (like ours), rear young to reproduce again" (Gottschall 2003). Such a directive echoes the command reported in the Book of Genesis to have been issued by God to all living creatures including humans: "Be fruitful

and multiply and fill the earth. . ." (1:26). The structuralist literary critic, J. P. Fokkelman observed in 1987 that "the overriding concern of the book [is]: life-survival-offspring-fertility-continuity" (Alter and Kermode 1987), and Steven Marx elaborated that idea in his discussion of generation, genealogy, and genetics in Genesis in 2000 (Marx 2000), but as of 2009 the application of self-conscious Darwinian studies to the Literary Study of the Bible remains only a promise.

Self-Identification

Science

As reflected in the preceding chronological account, The Bible as Literature/Literary Study of the Bible has traditionally defined itself by exclusion of science: first by distinguishing its subject matter from theology, which treated the Bible as God's revealed truth, and second from the "Higher Criticism," which treated the Bible as a historical artifact representing actual historical events. Some proponents of the Bible as Literature (Sidney, Donne, Blake, Frye) have claimed that the language of the Bible refers to visionary or imaginative reality distinct from the material, temporal reality referenced by the language of science. Ancient midrashic and contemporary postmodern exegetes reject the scientific principle of falsifiability and the logical law of contradiction and accept multiple mutually contradictory interpretations. Nevertheless, the Bible as Literature/Literary Study of the Bible has also incorporated methods that can be classified as scientific because of their appeals to supportive textual and archaeological evidence, inner consistency, principles of design and symmetry, as well as to the psychology of rhetoric and the classification of genres. Recent developments in ecocriticism applied to the Bible as Literature/Literary Study of the Bible abandon the exclusionary definition of the field and seek to make it compatible with disciplines conventionally regarded as scientific such as ecology, cultural geography, and evolutionary biology.

Religion

The Bible as Literature/Literary Study of the Bible does not identify as a religion, but can be considered as either a religious or nonreligious endeavor. Early literary biblical exegesis was usually done within the framework of theology to enhance the status and appreciation of the sacred text by illuminating its literary virtues. Until the sixteenth century such study was limited to a few people who could read, and in both Jewish rabbinic and Christian patristic traditions, interpretation was seen to be inspired by God or the Holy Spirit. Since the Renaissance, one strain of literary criticism considers poets to be prophets and the Bible as prophetic utterance stemming from a quasi-divine source within humans. Some historical criticism and postmodern literary criticism aims to highlight arbitrary, accidental, or erroneous features of the Bible to undermine claims of its religious significance.

Characteristics

As mentioned, the Bible as Literature/Literary Study of the Bible is defined by its distinction from both theological and from historical or scientific biblical studies. It is a blend of literary criticism and Biblical studies. However since Biblical studies are sometimes theological and literary criticism sometimes incorporates methods of historical or scientific disciplines, another distinction lies in its unstable and elastic definition.

Relevance to Science and Religion

The category and academic pursuit of The Bible as Literature/Literary Study of the Bible arose out of the Science and Religion Controversy of the nineteenth century. Scientific discoveries about the historical evolution of the received biblical texts and about the circumstances of their composition along with discoveries about geology and biology contradicted many traditional beliefs about the Bible's truthfulness and authority. The Literary Study of the Bible avoided this

controversy by creating new possibilities for finding meaning and value in the Bible as a work of art available to nonreligious people. Religion has inspired and in turn been strengthened by art, and in this sense the Literary Study of the Bible can enhance religious experience and support religious belief. Conversely, study of the Bible as Literature can widen scientific access to the richness and complexity of religious experience and can reveal ways that texts and their interpretations have motivated the behavior of readers. For example, in a general education course entitled "God and Nature," proposed for Cal Poly University San Luis Obispo for Spring 2010, a biologist will present current scientific research that explains the variety of life on earth with Darwinian principles, a religious studies scholar will compare the Genesis account with creation myths from other cultures, and a literary critic will examine the aesthetic design and the emotional appeals of the language of *The Origin of Species*, of the Bible and of the other creation myths.

Sources of Authority

As a blend of Biblical studies and literary criticism, The Literary Study of the Bible accords authority to researchers in both fields. Prestige of historical Biblical scholars usually depends on mastery of ancient languages, historical, geographic, and archaeological erudition and technical skills like paleography and epigraphy, as well as on standing within professional hierarchies. Prestige of literary critics depends more on breadth of learning, rhetorical eloquence, self-fashioned identity, and originality of positions argued. Publication in prestigious journals and employment at select universities counts for both. Authority also stems from textual sources, primary and secondary. Biblical authority is no higher than the authority of other literary texts. Generally in Biblical scholarship, the more ancient the material referenced the greater its authority. Literary criticism tends to value references to new trends and information from unexpected quarters.

Ethical Principles

Since the subdiscipline has neither a journal nor a professional organization and since its definition is somewhat elastic, it is hard to answer this question. One principle generally observed by participants is respect for readers who do not share the same view of biblical authority or similar interpretations of the meaning and significance of biblical texts.

Key Values

One is aesthetic: participants pursue discovery and elucidation of imaginative and intellectual beauty encoded in the Biblical text and its interpretations. Another is philosophical: the apprehension of truth and wisdom through various ways of understanding the Biblical text and through the revelation of errors or distortions. The values of nonviolence, gender, racial and ethnic equality, social justice, and environmental stewardship inform some literary readings of the Bible.

Conceptualization

Nature/World

Literature represents nature/world, i.e., creation, with words. The study of literature inquires not about the world of nature, but rather the world of words and images. The Hebrew Bible shows God creating nature with words. The New Testament includes the statement that “In the Beginning was the Word. . . and the word was God.” So both the Literary Study of the Bible and the Bible itself privilege verbal utterance over physical creation. However, insofar as the Literary Study of the Bible regards it as a historical artifact it treats the Bible as a product and representation of the natural and social world of its historical and geographic settings.

Human Being

Literary criticism examines the Bible’s alternate representations of the human being: it is created

male and female at the same time as the other animals by the words of God and it is molded male first out of earthen clay and then born female out of the male’s body. Literary Study of the Bible relates these stories of origin to other discourses in the Bible about the relationships between men and women and between humans and animals. It tends to regard these stories of the creation of humans by God as products of the human imagination.

Life and Death

Literary Study construes the Bible’s stories of the origin of life either as contradictory to the scientific narrative of evolution or as analogous to it. It devises figurative meanings of the story of the origin of death as punishment for transgression and as a consequence of gaining the knowledge of good and evil and observes the symmetries created by New Testament images of death overcome by the resurrection of Jesus and the community of the saved.

Reality

Concepts of reality are classified as (1) “realist,” meaning that reality consists of formal abstract universals encoded in words and symbols (2) “nominalist,” meaning that reality consists of material particulars arbitrarily categorized and labeled by formal abstractions, words, and symbols, and (3) “conceptualist,” meaning that reality consists of a combination of formal abstractions and material particulars. All three have adherents within the Literary Study of the Bible. The realist view manifests in formalist, typological and archetypal criticism, which regards the text as absolute. The nominalist view informs historical and post-structuralist readings. The conceptualist mix is adopted by most critics in actual practice.

Knowledge

Knowledge in this field is largely textual, knowing what is in the Bible, understanding its languages – ancient and modern, explicit and occult – and being attuned to subtle detail and hidden pattern. Some knowledge is intuitive: the ability to read between the lines, discover

significance in the unstated, discern correspondences, and find meaning in unusual psychological states. Knowledge is accumulated by study of the text and its interpretations, by understanding literary theories, analytical vocabulary, and lexicons of symbol and archetype. The Literary Study of the Bible also values non-textual scientific knowledge about the provenance of the text, the history and geography of its settings, and the findings of comparative religion.

Truth

Literary Study of the Bible elaborates the notion that the truth of the text's assertions is found not only in their literal sense but in figurative, allegorical, or "spiritual" senses arrived at through knowledgeable interpretation. Theological notions of the Bible's "inerrant truth" assert that as God's Word, the Scriptures contain truth that no human inquiry, scientific or otherwise, can fully comprehend. Both the Book of Proverbs and the Gospel of John claim that the Word of the text precedes the creation of the world. The Literary Study of the Bible reflects on what is meant by such paradoxical utterances. Adherents of New Criticism assume that the Bible in whole and in parts, like other literary works, has a fullness of meanings that can be approached but never fully grasped by interpretation. Historical and scientific forms of Literary Study of the Bible find truth by placing the Bible in its material and cultural context – referred to by some scholars as its *Sitz im Leben*.

Perception

Perception is closely related to "knowledge." Realist-leaning literary critics associate perception with "vision" of a nonmaterial higher-order reality apprehensible through dreams and other altered psychological states. The Bible itself is full of representations of such visions and auditory perceptions, which realist interpreters identify with and sometimes share. Nominalist-leaning critics regard perception as accurate only if backed by scientific methods requiring falsifiable, repeatable, intersubjectively confirmable evidence. They seek to explain Biblical visions as hallucination. Conceptualist-inclined

interpreters regard perception as a synthetic creation of subject and object and find the range of vision recorded in the Bible worthy of further investigation.

Time

The Hebrew Bible/Old Testament begins with the creation of Time – "the first day" – by God, who presumably exists outside of time. The Christian Bible concludes its temporal narrative of the history of the world with an account of the end of time and its replacement by a new heaven and new earth, also presumably eternal. With utterances like God's I AM WHO AM in Exodus 3:14 and Jesus' "Before Abraham was, I AM," in John 8:58, the text suggests a supertemporal realm of existence pondered by Biblical interpreters like Augustine and Aquinas and rendered artistically by Dante and Bosch. "Synchronic" literary criticism of the Bible treats the whole text as contemporaneous and present simultaneously to the reader, especially in its employment of typology. "Diachronic" criticism treats the text as an artifact that evolved in the past over a long temporal interval.

Consciousness

Some Literary Study of the Bible treats its sequence of portrayals of God from beginning to end as a study in an evolving consciousness, one that learns by experience and by interaction with its human offspring in history – for instance, Jack Miles' *God: A Biography* and *Christ: A Crisis in the Life of God* (New York: Alfred A. Knopf 1995).

Reason/Rationality

As a secular academic discipline, Literary Study of the Bible values rationality and reason, which it applies to understanding even those Biblical texts that appear irrational or are claimed to be superrational.

Mystery

The Bible is filled with incident and language that is perplexing, enigmatic, and uncanny. Protagonists like Abraham, Job, and the disciples of Jesus and antagonists like the Pharaoh or the Roman

authorities are mystified by God's words and actions. Such mystification promotes wonder and awe, which can contribute to the authority of the divine or the divinely inspired speaker and can increase reverence for the text. Literary analysis can either intensify or undermine such responses on the part of the reader.

Description

Biblical studies constitutes a subdiscipline of the academic study of religion. Integral to that more encompassing discipline is the examination of religious texts and how they have been and are used within particular religious traditions. Specifically, biblical studies focuses on those religious texts deemed sacred and authoritative (i.e., “scriptural”) by Jews and Christians. Jewish scriptures are frequently referred to by the Hebrew acronym, “*Tanakh*,” used to designate the three parts of the canon: *Torah* (the Pentateuch), *Nevi'im* (prophets), and *Ketuvim* (the writings). The Christian Bible comprises both the Jewish scriptures and Christian writings called the “New Testament.” Ultimately, the goal of biblical studies is to explore fully what S. Schneiders has felicitously described as three “worlds” of meaning: (1) *the world behind the text*, that is, the historical context in which the biblical writings arose; (2) *the world of the text*, that is, the linguistic reality presented in the biblical texts as they now stand, regardless of how they came to be; and (3) *the world before the text*, that is, the engagement with these religious texts by past and present readers/interpreters (Schneiders 1991).

Noteworthy, recent developments in biblical studies may be highlighted in terms of Schneiders’ taxonomy. To illuminate the “world behind the text,” biblical studies has paid increasing attention to noncanonical religious texts that were produced contemporaneously with the works deemed scriptural. Scrutiny of Jewish and Christian Apocrypha and Pseudepigrapha, the Dead Sea Scrolls, and Gnostic writings reveals the religious diversity within Judaism and Christianity as they developed during the biblical era. Archaeology and the study of material culture continue to be important complements to biblical studies. The 2001–2006 collaboration that resulted in the restoration, translation, and publication of the so-called Gospel of Judas is a parade example. In coming to terms with the “world of the text,” biblical studies has acknowledged the importance of the postmodern, “linguistic turn.” Narrative criticism, reader-response criticism, and deconstructive criticism are widely employed in biblical studies at the beginning of the twenty-first century. In elucidating the “world before the text,” biblical studies now benefits from the insights of postcolonial readers, who not only sensitize Western critics to the role the Bible played in imperialistic, colonial expansion but also offer hermeneutical approaches that build upon and challenge the hegemony of the historical-critical method.

In light of these developments, one senses a transformation underway in the practice of biblical studies as a subdiscipline. No longer a mostly historical or “historicist” enterprise that seeks to drive a wedge between exegesis (narrowly understood as recovering what a text *meant*) and hermeneutics (discovering what a text might *mean*), biblical studies has become more conscious (and accepting) of the fact that its work may be carried out as both an *etic* and an *emic* endeavor. When biblical studies is pursued impartially with an outsider’s (etic) perspective, the task is primarily descriptive and analytical, the goal of which is to understand how religious communities have appropriated biblical texts as scripture, as “guides for life” (Sanders 1976: 531–560). However, biblical scholars can and often do work from

the perspective of an insider (emic), that is, interpreting scripture while standing within a religious tradition (Judaism or Christianity) and perhaps holding to a particular construal of that tradition (i.e., belonging to a specific branch, denomination, confessional stance of Judaism or Christianity), or an ideology (feminist, womanist, queer, etc.). The etic approach is not necessarily inimical to belief, practice, or ideology; indeed, it can and does provide insights and correctives that insiders welcome. Similarly, careful attention to the ways in which the Jewish and Christian scriptures have been and continue to be “adaptable for life” (Sanders, *ibid.*) among practitioners or impact the broader culture in both positive and negative ways provides the biblical scholar with a more profound understanding of the function of sacred texts.

Self-identification

Science

As a subdiscipline of the study of religion, biblical studies does not identify itself as a science, in the narrow sense of the word. If science is defined as a way of knowing whose goal is to understand a universe made up of material and energy, a way of knowing that seeks to understand the natural world by building theories with broad and lasting explanatory value, logically constructed of facts built upon a foundation of direct and indirect experimentation, generalized laws, and confirmed hypotheses, then biblical studies cannot be considered a way of knowing of that sort. It clearly finds its moorings in Renaissance humanism.

Nevertheless, some do talk about the “science” of biblical studies. Since the nineteenth century, the historical-critical method has dominated biblical studies. The Jewish rationalist and philosopher Baruch Spinoza (1632–1677) was an important harbinger of that approach. Insisting that scriptures be read objectively, like any other text, Spinoza was one of the first to study the Bible “scientifically.” He was keen on investigating the historical background of the Bible’s constituent texts, classifying and comparing their

literary genres, and posing questions of authorship. Following Spinoza’s lead, nineteenth- and twentieth-century historical critics, chary of any hermeneutic shaped by dogmatic or confessional commitments, attempted to determine what the biblical texts’ meaning would have been in their original, ancient contexts. For that reason, during the past 100 years or so, biblical studies has been primarily concerned with establishing the origins of texts, with ferreting out “authorial intention,” with characterizing the original audience(s). It has also been concerned with how biblical texts were preserved and transmitted and how to describe the historical processes by which they achieved their present canonical status.

By the final quarter of the twentieth century, the limits of the historical-critical method were abundantly apparent. Biblical studies has displayed a dogged rigor in reinventing itself. The subdiscipline has been increasingly willing to acknowledge the provisional nature of its accomplishments. Methodological conversations have never been so animated. New alliances have been forged with the social sciences. In the eyes of some, the latter move has lent biblical studies a certain scientific cachet, despite its firm grounding in the humanities.

Religion

“Historical” fundamentalism is a distinctly Protestant, Christian phenomenon that arose in America in the late nineteenth and early twentieth centuries as a response to the “modernist” challenges of higher biblical criticism, Darwinian evolutionary theory, and Spencerian “social” Darwinism. It has as a cornerstone of its construal of the Christian religion a belief in biblical inerrancy. Fundamentalists are committed to the notion that the Bible (in its original autographs) is divinely inspired and, by virtue of that inspiration, guaranteed to be without historical, scientific, or theological error. As it developed, Christian fundamentalism has given rise to a branch of biblical studies whose primary aim is to bolster biblical inerrancy as the primary tenet of religious belief. James Barr terms this “Biblicism,” a form of Christianity in which the Bible is the supreme religious symbol, comparable to

Christ, the “accessible and articulate reality, available empirically for checking and verification, that provides for the lines that run through the religion and determine its shape and character” (1978: 36). Insofar as fundamentalist biblical studies functions to protect the Bible against all other modes of interpretation, it constitutes a cultus for a quite separate religious form.

Characteristics

Biblical studies is distinguished by its methodological pluralism and interdisciplinarity. Expert training in ancient languages is almost always the starting point. Scholars of the Hebrew Bible (Old Testament) are expected to achieve a high level of proficiency in ancient Hebrew and Aramaic. Comparative study of other ancient Near Eastern Languages (e.g., Ugaritic, Akkadian) is usually undertaken as well. Scholars of the Christian scriptures master Greek and frequently Coptic, Latin, and Syriac. Language study is complemented by work in humanities-based disciplines such as history, literary theory, gender, and cross-cultural studies. Increasingly, biblical studies draws upon the methods of disciplines housed in the social sciences, especially anthropology, sociology, and linguistics.

Relevance to Science and Religion

Science and religion are potent forces in contemporary life. Questions about the relationship between science and religion – whether construed as conflict, independence, dialogue, or integration (Barbour 1997: 77–105) – have come to the fore, especially in the USA. The recurrent, passionate debates and court trials about what ought to be the theoretical basis for teaching biology in the science classes of American public schools (evolution, intelligent design, or both) have pitted not only religion against science but the scientific method against biblical interpretation. Americans continue to replay the Scopes trial – over and over again. Biblical studies is poised to *and should* offer an important corrective.

Drawing upon its traditional strengths and methods, biblical studies is able to contextualize the biblical worldview. While writing in a prescientific age, the authors of the biblical texts were neither unconcerned with nor ignorant about the natural world. But the biblical authors were not engaged in “doing science.” Their empirical observations and comments are epiphenomenal to a far bolder religious enterprise, one that biblical studies can clarify. More importantly, biblical studies can make an even greater contribution by addressing the role of the Bible in the history of science (see section “[Relevant Themes](#),” below), a perspective that has been almost entirely lacking in recent debates.

Sources of Authority

As a subdiscipline of the academic study of religion, biblical studies is usually carried out in the context of accredited institutions of higher education: colleges, universities, theological seminaries, and schools. Scholars of biblical studies normally hold advanced degrees, usually the Ph.D. or its equivalent. One of the oldest learned societies in America, The Society of Biblical Literature (SBL), is also one of the largest and boasts a large and growing international membership. Many members of the SBL also hold membership in the American Academy of Religion (AAR). Both the SBL and the AAR are constituent members of the American Council of Learned Societies. Both publish highly respected, refereed journals: *The Journal of the Society of Biblical Literature* and *The Journal of the American Academy of Religion*. Both have sponsored dissertation and monograph series. These are but two among a host of professional, academic organizations and journals (American and international ones) to which scholars of biblical studies contribute. Biblical scholars may also seek formal approval or certification (e.g., in the Roman Catholic Church, an “imprimatur”) of their work that attests conformity to the doctrine and discipline of a religious body, or the work may be published under the auspices of a religious institution.

Ethical Principles

The ethical principles that guide biblical studies are chiefly those of the academy, those that pertain to intellectual integrity. Additionally, biblical scholars share the ethical principles of the discipline of religious studies. Thus, they strive to maintain an objective respect for religious practitioners whose sacred texts they study. Humility in approaching the complex phenomenon of human religiosity is enjoined. All definitions of religion are recognized as provisional and necessarily incomplete. Broad-sweeping generalizations are eschewed; comparative taxonomies are offered with great caution. Because early Christians appropriated Jewish scriptures as their own, and in light of a tragic history of Christian anti-Judaism, biblical scholars are especially sensitive to latent prejudices embedded in the subdiscipline.

Key Values

As mentioned previously, the subdiscipline of biblical studies embraces methodological pluralism and interdisciplinarity. Beyond that, the key values of biblical studies are reflected by the thoroughgoing way in which the subdiscipline has confronted the challenges of modernity in thinking about religion and religious texts. For example, it has certainly not shied away from the notion that sacred texts are human constructs. The rigor with which it has pursued form-critical, source-critical, redaction-critical, text-critical, and archeological avenues to their limits bears witness to that courage. Moreover, biblical studies seriously entertains the profound implications of the “linguistic turn,” the recognition that reality is mediated by language. Biblical scholars recognize that religious texts create cultural worlds. People who embrace biblical religion think about and experience the world in ways that are fundamentally shaped by language and texts. That being the case, the study of biblical texts requires the study of human activity not just written words. Biblical studies seeks to illuminate not only the content of biblical texts, but also their context and

use, attending the larger field of cultural activities, including the ways religious texts have been, *and are*, read, spoken, and performed. Comparatively speaking, this level of sophistication in approaching religious texts is scarcely equaled in the study of the world’s other great religious traditions and can serve as a model for other subdisciplines of religious studies.

Conceptualization

In discussing the following concepts, a prefatory note is necessary. Topics of this sort are usually taken up under the aegis of “biblical theology.” As Dennis Olson of Princeton Theological Seminary explains, biblical theology reflects a *constructive* engagement with the Bible that “seeks to provide greater conceptual articulation, coherence, or development of the Bible’s texts, ideas, metaphors, stories, and poetry involving God, humans, and the world in dialogue with various methods, contexts, and historic theological traditions” (*New Interpreter’s® Dictionary of the Bible* I.461–465). In others words, biblical theology cannot help but be concerned with the *world before the text*. Since the 1960s, the arena of biblical theology has been a highly contested domain. Because biblical texts are themselves diverse (produced over a millennium and reflecting the religious aspirations of varying communities) and because interpreters bring a host of methods and perspectives (etic and emic) to the effort, biblical theology is fraught with difficulty. There are some who are convinced that biblical theology either runs the risk of reductionism or invariably imports dogmatic, systematizing assumptions. What follows reflects, admittedly, an attempt to be cautiously descriptive, privileging the *world behind the text* and the *world of the text*. In doing so, it attempts to suggest how the work of biblical studies, when directed toward these selected *topoi*, can uncover hermeneutical “talking points,” which might serve as the basis for an enhanced, more nuanced conversation between the scientific community and those for whom these religious texts hold particular significance.

Nature/World

Biblical studies is quick to note that the English word “nature” derives from the Latin *natura*, which is most often used to translate the Greek word *phusis*. There is no corresponding word in Hebrew. In the Hebrew Bible (and echoed in the Christian New Testament), the entire cosmos, that is, “nature,” is designated by the phrase “heavens and earth.” According to the creation ► [myths](#) of Genesis, the heavens and the earth (all the entities that are not the product of human invention) are result of God’s creative activity, God’s “work.” In the Hebrew Bible, God “creates” by ordering chaos and forming the cosmos out of primordial waters. The Bible – in both its Jewish and Christian portions – presents the creation as a unified whole. The stories that narrate the creation of the physical/material realm are neither separate from nor secondary to those that account for the appearance of human beings. In the Christian New Testament, the concept that God created the cosmos *ex nihilo* (out of nothing) emerges more fully (Romans 4:17; Hebrews 11:3), though the idea is latent in noncanonical Jewish texts from the Hellenistic era. As the product of God’s creative and sustaining activity, nature is also revelatory; it points beyond itself to its source, that is, God (See *New Interpreter’s Dictionary of the Bible*, “Nature, Natural Phenomena,” IV.238–239).

Human Being

As noted above, biblical studies deals with religious narratives that assume human being, the human person, is the result of God’s creative activity. Taken as a whole, the biblical tradition is singularly uninterested in speculation about human essences. It does not belabor the physiology of being (as bipartite: body/soul or tripartite: body/mind/soul). It affirms a simple – though hardly *simplicistic* – theological anthropology: Human being comprises a psychosomatic unity of life force/vitality (Hebrew: *nephesh*) and material physicality. The human person does not possess a soul; the human person *is* soul (Genesis 2:7).

The two creation ► [myths](#) of Genesis 1–2 are chiefly concerned to describe the *rôle* of human

being in the created order rather than detailing the processes by which human being came into existence:

Genesis 1 – While scholars continue to debate about the precise implications of what is meant by the account of Genesis 1 (assigned by historical criticism of the Pentateuch to the Priestly strand of the postexilic period) that says that humans were created in the “image and likeness of God” (Genesis 1:26–28), most agree that the focus there is on the intended *rôle* envisioned for humanity, viz., that of being God’s representative in the world, holding primary power of governance over it.

Genesis 2 – In the second creation story of Genesis 2:4bff, which historical criticism attributes to the so-called Yahwist tradition, humanity is formed from already existent, arable soil (Genesis 2:7). Employing a Hebrew pun on a verbal root that can mean both “serve” and “till” (Genesis 2:15), the Yahwist describes humanity’s place as that of “farmer from farmland,” as “slave of soil,” an account whose focus, then, is on humanity’s relationship to, solidarity with, the created order, the physical universe.

Both of these narrative strands shape the understanding of the human person throughout the Christian New Testament (See *New Interpreter’s Dictionary of the Bible*, “Humanity, NT” and “Humanity, OT,” II.907–912).

Life and Death

In the biblical worldview limned by this subdiscipline, the cosmos apart from the animating activity of God is void and lifeless. God is the source of vitality; the world cannot produce life on its own. Since all that lives depends upon God for its existence, to *live* is to find one’s place in appropriate relationship with God. Thus, biblical thought betrays relatively little interest in cosmology, biology, or philosophy, favoring instead the moral dimension of existence (see “[Knowledge](#)” below, and *New Interpreter’s Dictionary of the Bible*, “Life,” III.655–661).

In the Yahwist’s account of creation in Genesis 2, the prospect for humanity is long life lived in fellowship with God (the more abstract notion

of *immortality* is not introduced in this context). Mortality – death – is a consequence of human disobedience. Moreover, as a result of sin, life expectancy for humans decreases. The genealogy of Genesis 5:27 reports that Methuselah lived 969 years. By comparison, Abraham, the progenitor of the Jewish people, lived only 175 years (Genesis 25:7). For the psalmist, the normal span of a human life is reckoned as 70 years, 80 at the outside (Psalm 90:10).

Reality

Generally speaking, the biblical tradition is not given to discrete, philosophical meditation/speculation about the nature of reality as such. That God is the source of existence as human beings experience it is the fundamental, operative presupposition in both Jewish and Christian scriptures. Nevertheless, apprehension of that reality is elusive: Moses was granted only to see God's "backside" (Exodus 33:18–23); Paul admits that "we see by means of a mirror, in an enigma" (*di' esoptrou en ainigmati* – 1 Corinthians 13:12). To glimpse the richness and subtlety of the Bible's conception of reality, biblical studies pays careful attention to metaphors found in biblical poetry, to the ways in which the verb "to be" is manipulated in narratives, to words that can be translated as "life," and to expressions such as "there is" or "there is not."

Knowledge

Biblical texts bear witness to the fact that humans can and do rely upon the senses to deliver mostly reliable information about the nature of things – animate and inanimate – and for negotiating existence in world. Sensory information requires the complements of intuition and rational processes. Taken together, these can lead to "true" (see below) knowledge.

Knowledge goes beyond information. It is the basis for moral agency, right action. The Bible's concern is not with articulating an epistemology. Rather, knowledge is assayed in terms of moral understanding, embedded in an unfolding narrative about covenantal relationality (See *New Interpreter's Dictionary of the Bible*, "Knowledge," III.539–546).

Why "moral understanding," not "ethics"? One must take seriously the nature of biblical texts. They are not philosophical treatises. Wayne A. Meeks, Woolsey Professor Emeritus of Religious Studies at Yale University, makes an important distinction between biblical morality and philosophical ethics: "I take 'ethics' in the sense of a reflective, second-order activity: it is morality rendered self-conscious; it asks about the logic of moral discourse and action, about the grounds for judgment, about the anatomy of duty or the roots and structure of virtue. It is thus, as the *Oxford English Dictionary* has it, 'the science of morality'" (1993: 4–5). By contrast, biblical stories, Psalms, prophetic pronouncements, Gospels, and letters do not seek to engage readers in ethical reflection. Rather, their aim is to *shape religious communities* concretely by articulating a set of practices and by fostering their inculcation with *paranaesis*, that is, moral exhortation.

The *sine qua non* of true knowledge is *wisdom* (See *New Interpreter's Dictionary of the Bible*, "Wisdom in the NT" and "Wisdom in the OT," V.865–875). Wisdom denotes a depth dimension of knowledge. Wisdom leads to proper relationships, to harmony with God, with one's fellow humans, and with the world. In some portions of the biblical tradition, wisdom is *personified* (often as a female) and is exalted as the creative agent by which the world was brought into existence and is governed (see Proverbs 1, 8, 9).

In the biblical world, revelation is also a source of knowledge, of wisdom. Ultimately, one of the animating features of the biblical narratives is the fact that human perplexity about the elusive nature of reality (see above) and the need for guidance is met by God's self-revelation. Deuteronomy 29:29 captures this perfectly: "The secret things belong to the Lord our God, but the revealed things belong to us and to our children forever: to observe all the words of this law." In the Christian Gospel of John, Jesus is portrayed as the human embodiment of God's *Logos*, God's "word," God's "reason/logic," and God's "wisdom" (John 1:14). Those who believe that Jesus is God's self-manifestation, who follow him and obey his commandments, find "the way, the truth and the life" (John 14:1–6).

Truth

Biblical words for truth (Hebrew = *‘emeth*; Greek = *alētheia*) are used to express a number of concepts. Two may be singled out. Truth is first and foremost a characteristic of *action*; one *enacts* “truth” by keeping promises, acting justly, fulfilling an obligation, showing piety, etc. Thus, both the Hebrew and the Greek words frequently render “truth” in terms of “reliability,” “faithfulness,” and “trustworthiness.” Secondly, writers in both the Hebrew Bible and the New Testament value “truth” in the sense of correspondence between words and reality. When used to convey that meaning, “truth” in the biblical sense implies “accuracy” and “honesty” in the use of words to make some reality evident (See *New Interpreter’s Dictionary of the Bible*, “Truth,” V.681–686).

Perception

While biblical texts take for granted the fact that humans can and do rely upon the senses to deliver mostly reliable information about the nature of things – animate and inanimate – and for negotiating existence in world, they also betray an awareness that reality is not conterminous with sense perception. The senses can deceive. In the New Testament, Paul (a Jewish Pharisee and Christian indebted to intertestamental Jewish interpreters) states that the entire creation participated in the fall of humanity and that it, too, is alienated from God. Subsequent Christian interpreters, especially during the Protestant Reformation, argued that Paul’s notion of a fallen creation implied that the self-revelatory nature of the cosmos became diminished and opaque and human ability to perceive nature aright skewed. This interpretive trajectory has had important implications for how some Christians evaluate the claims of science; there are Christians who hold that, apart from grace that comes from belief in Christ, humans are incapable of understanding the natural world.

Time

Since James Barr, then Professor of Old Testament Literature and Theology at the University of Edinburgh, wrote his groundbreaking *Semantics of Biblical Language* in 1961 and his subsequent

monograph, *Biblical Words for Time* in 1962, biblical studies has been tendentially reiterating that the thought world of the authors of the Hebrew Bible and the Christian New Testament ought not be shoe-horned into anachronistic, abstract, inappropriately comparative categories. Rather than offering meditations on the nature of “time,” biblical texts provide a lexicon for describing the movements of celestial objects. Day, night, week, month, and year are the basic units of observation. Sunrise and sunset and the waxing and waning of the moon are coordinated with agricultural cycles. Seedtime and harvest are intimately tied to cultic festivals, days set apart as “holy.” Time, then, is not so much a dimension to be contemplated but a set of relationships to be negotiated. When that is recognized, the enumeration of the first 3 “days” in Genesis 1:3–13 prior to the creation of the sun and the moon on the fourth is not incongruous. The creative “week” is not so much about 24-hour days as it is about a rhythm established by a plan that brings into existence a firmament first, then lights to “occupy” the firmament, then seas and dry land, followed by the life-forms that populate both, all of this related, ultimately, to the observance of Sabbath.

While it is granted that “a 1,000 years in [God’s] sight are like a day” (Psalm 90:4; c.f., 2 Peter 3:8), the God of the Hebrew and Christian religions, who is beyond “time” as humans experience it, is nevertheless self-revelatory and intervenes in human affairs. Epiphanies are made to particular persons, in concrete places, at specific times. Decisions are made as a result. Actions follow. Modes of reckoning and recording time and concomitant elements of calendrical calculation and history writing are ancillary to religious purposes. Events are arranged in a constellation of significances.

Temporal references in the Bible are underlined in ways that indicate their *momentous* character. The most common Hebrew word typically translated as “time” (*‘eth*) is usually accompanied by prepositions, adjectives, demonstrative pronouns, and modifying phrases (“*in* the time,” “*near* the time,” “*at that* time,” “*at the* time of your deliverance,” etc.). In the Christian New

Testament, following the lead of the Septuagint (the Greek translation of the Hebrew Bible), concern to describe events as having moment is indicated by a decided preference for *kairos* (“appropriate” or “decisive” time) as opposed to *chronos* (“workaday” time). This is nowhere more evident than in the Christian Gospel of John, where the culminating event, Jesus’ Passion, is encapsulated as his “hour” (*hōra* – see 17:1). Finally, several writings in the Jewish scriptures and all of those in the Christian corpus are colored by eschatological/apocalyptic expectations. Time is religiously meaningful and teleological (See *New Interpreter’s Dictionary of the Bible*, “Time,” V.595–600).

Consciousness

The Bible details no Cartesian breakthrough (“*Cognito ergo sum*”). There is no Hebrew word that is even roughly translatable as “consciousness” (See *New Interpreter’s Dictionary of the Bible*, “Conscience,” I.719–726). The stories of Genesis 2–3, which biblical studies regards as ► **myths**, drop tantalizing hints, sweetly perfumed handkerchiefs that beckon interpretive suitors to retrieve. When the *adam* is animated by God’s breath in Genesis 2:7 and becomes a *nephesh* (see above, “**human being**”), is a coming to consciousness implied? The text is not explicit. When the human male is given the task of naming the animals (a role tantamount to being cocreator in comparative, ancient Near Eastern thought) and recognizes that among them is no suitable mate, does he acquire for himself reflexive self-awareness (Genesis 2:18–20)? Again, interpreters are left at sixes and sevens. Maybe the awakening comes when the woman, created by the Lord out of the *adam*’s (“clod man’s”) rib, is presented to him and he declares, “At last, this is bone of my bone, flesh of my flesh” (Genesis 2:21–23). Doesn’t the aftertaste for having eaten the forbidden fruit of the tree of the knowledge of good and evil count for something (“their eyes were opened, and they knew that they were naked” – Genesis 3:7)? For the most part, historical critics hold back. The interpretative tradition, both Jewish and Christian, has been and is more solicitous.

Biblical scholars turn in elsewhere. They attend to the laconic pronouncements of the “Preacher” in the Hebrew Bible’s *Qoheleth* (Ecclesiastes). Writing in the first person singular, the text reflects an astute albeit resigned, world-weary consciousness (Ecclesiastes 3:7) that is altogether unique. Its place among the sacred writings of the Jews was still being debated in the 2nd century of the Common Era. The Book of Job reflects a sober, hard-won consciousness about himself and his place in the world as he attempts to come to terms with apparently unjust suffering. The Psalms, for example, are rife with explicitly introspective, self-reflective passages.

The Greek word for consciousness that would have been available to early Christian authors, *suneidēsis*, is not used by the authors of the Synoptic Gospels (Matthew, Mark, Luke) or the Johannine literature (Gospel of John, 1, 2, 3 John). Of the 27 occurrences in the New Testament, more than two-thirds are found in Paul’s letters. In most instances, English translations render *suneidēsis* as “moral consciousness” or simply “conscience,” implying the existence of an internal capacity [of the soul?] that guides conduct, that provides laws, that judges or sanctions behavior, and that renders verdicts of guilt or innocence. Biblical studies’ scholars are quick to point out that this later, shifted sense, with its penchant for legal metaphors, is an imposition on the Christian texts and skews readings (see especially Krister Stendahl’s watershed essay, “Paul and the Introspective Conscience of the West” cited below). With Timothy 4:2 and Titus 1:15 being the two notable exceptions, *all* of the New Testament occurrences of *suneidēsis* point to a more general conception of a human consciousness in touch with surroundings and self, which is, secondarily, capable of acknowledging shortcomings, producing bad feelings, and altering behaviors (Stendahl 1976).

Rationality/Reason

See sections “**Human Being**” and “**Knowledge**” above. As noted there, the ultimate goal of reason is to attain wisdom, the sure knowledge of God as

the source of all that is, the one who orders chaos. In biblical thought, the primary endowment that distinguishes human beings from animals is rationality, the ability of reason. Human governance in the world as God's representative is inextricably linked to thought and the ability to communicate thought, to translate it into action by means of speech acts. Thus, the proximate ends of ratiocination are regulatory. As the "governor" of life, reason controls the passions; it rules the emotions; it steels courage and banishes fear. Self-control is the benchmark, the rational life. Reason, however, may be misdirected. Or it may overstep its bounds. It can lead to pride, to self-assertion, to self-idolatry, and thus, ironically, to profound ignorance. In the Jewish scriptures, the book of Daniel recounts one of the most vivid examples of how hubris can lead to the loss of rationality and of one's humanity. The Babylonian king, Nebuchadnezzar, was struck by madness, *insania zoanthropia*, which drove him away from human society to dwell with animals, where for an extended period he ate "grass like oxen, his body bathed with the dew of heaven until his hair grew as long as eagles' feathers and his nails became like birds' claws" (Daniel 4:28–37). When he was restored to his rightful place as king, Nebuchadnezzar says that his "reason" (Hebrew = *manda'*) returned to him.

Mystery

See section "Time" above. In the Hebrew Bible, "mystery" (Hebrew = *razah*) first appears in Daniel (Daniel 2:18, 19, 27, 30, 47; 4:9). The word recurs in the apocalypses of the Pseudepigrapha and in the scrolls discovered at the Dead Sea. Mystery is revealed by divine agency to a seer. In Daniel and the intertestamental Jewish texts, the content of mystery is cosmological: Secrets about the function of universe are unveiled, secrets that simultaneously reveal the plan for how God's purpose will achieve its predetermined end.

The writings of the Christian New Testament presuppose this background. The Greek word for mystery (*mustērion*) occurs 27 times in those writings, 20 of which are in the letters of Paul. The content of the eschatological mystery,

according to Paul, may seem more narrowly defined, but to Paul's way of thinking, it is ultimately more astonishing and startling: The revelation (*apokalupsis* – Galatians 1:12) of the crucified and vindicated Messiah (Jesus) adumbrates God's previously hidden intent to include Gentiles with Jews as God's people (see Romans 11:15). In every other instance in the New Testament, mystery is a portmanteau for conveying two ideas at once: (1) it refers to hidden knowledge that will be unveiled by God (apocalyptic secrecy) and (2) it pertains to the *telos*, the divine purpose, in history (See *New Interpreter's Dictionary of the Bible*, "Mystery," IV.185–187).

Relevant Themes

Ian G. Barbour has outlined four ways for construing the relationship between science and religion: conflict, independence, dialogue, and integration (1997: 77–105). At present, sustained, substantive interchange between the subdiscipline of biblical studies and the scientific community is, unfortunately, minimal. For example, when, in 2006, Richard Dawkins, esteemed biologist and the Charles Simonyi Professor of the Public Understanding of Science in Oxford University, leveled his broadside against religion, including an outright assault on the God of the Hebrew Bible, whom he describes as "arguably the most unpleasant character in all fiction: jealous and proud of it; a petty, unjust, unforgiving control-freak; a vindictive, bloodthirsty ethnic cleanser; a misogynistic, homophobic, racist, infanticidal, genocidal, filicidal, pestilential, megalomaniacal, sadomasochistic, capriciously malevolent bully" (2006: 31), he hardly got a rise from specialists in the biblical studies. The guild paid little attention to his equally vituperative characterization of the New Testament theology as "vicious, sadomasochistic and repellent...barking mad" (2006: 253). That frosty silence does not connote the field's entrenchment in a position of either conflict or independence. Rather, representatives have adopted a mostly aloof disdain for the way in which Dawkins and his ilk (Sam Harris,

Christopher Hitchens, Daniel Dennett, etc.) superficially cast biblical religion, indeed all of religion, in fundamentalist terms (see section “Religion” above).

Barbour’s hope, shared by many in biblical studies, is to identify points of contact that would allow for meaningful dialogue. Barbour urges scientists and religionists to interrogate the presuppositions that motivate their respective pursuits, their mutual concern with “limit questions,” to examine the methodological parallels that exist between the disciplines, and to acknowledge their common interests in nature. Such an investigation, he believes, may provide an avenue to authentic engagement.

Answering Barbour’s call, John Haught, director of the Georgetown Center for the Study of Science and Religion, has pointed the way. He documents an emergent awareness among scientists of the “fundamentally narrative character of nature” (2003: 67). Scientists who understand the cosmos as *story* have come to “read” physical laws not as final explanation but as the grammatical framework – the essential, recurrent, predictable constraints – for emergent novelty and for bringing the “story” to expression. “Analogously,” Haught concludes, “the strict Darwinian ‘rules’ of adaptation and selection, along with the laws of physics and chemistry are ‘grammatical’ requirements of any conceivable life-story” (2003), a story that science seeks to “read” and “interpret.”

Working quite independently of Haught, Kenneth Miller, professor of biology at Brown University, frames science’s “story” in this way: “By any standard we live in a universe that is simply brimming with evolutionary possibilities. Our planet is one place where those possibilities have come to fruition. Not only did life emerge on this planet, but life mastered it. It adapted to conditions on the earth and then it changed them. It altered the gases in the atmosphere, reshaped the chemistry of the oceans, and remade the land forever. Life explored the possibilities of existence on Planet Earth, and evolution drove that exploration. Evolution’s winners were the organisms that most successfully found a pathway to change and as a result have come to dominate

existence on our planet. We are among those organisms, but we possess something special, something that no other organism to our knowledge has ever had—the ability to see and to understand how we came to be” (2009: 134).

Miller goes on to interpret this narrative in terms of an “evolutionary cosmology.” While evolutionary cosmology reckons with a view of the universe in which human existence in the living world is an inherent part of nature itself, it is also a view of human being that brings with it awesome responsibility. “Evolutionary cosmology not only promotes a powerful ethic of environmental stewardship, but it places an extraordinary premium on scientific learning and understanding. . . . Science is indeed a human activity, with all of the faults and failings that attend any human creation, but it is also a human creation that continues to promise to add greater insight, greater understanding, and greater depth to our lives” (2009: 156).

As the survey of concepts in “Conceptualization” above reveals, these sentiments are ones with which biblical studies resonates. The subdiscipline of biblical studies focuses on religious texts. In communities for whom they are sacred scripture, these texts reveal the nature of reality beneath the surface of things, including human existence itself. For both insiders and outsiders, these texts do not yield their secrets readily; they require interpretation. Science explores the universe, itself a “text.” Science seeks to discern the reality of nature, of what is going on beneath the surface, often transcending empirical observation. Hard-nosed materialism does not settle for easy explanations; theories are hard won. The quest for depth motivates both enterprises.

Perhaps, it is not too much of a stretch to say that both science and biblical studies wrestle, fundamentally, with how to read “texts” appropriately, that is, with hermeneutics. Viewing them as ways of reading, albeit *distinct* ways of reading, promises to bring science and biblical studies profitably into dialogue. Moreover, historical examples of how the Bible’s readers have both sparked and questioned scientific interpretations – and vice versa – can

be illuminative. It is worth remembering that almost as groundbreaking as the publication in 1859 of Darwin's *Origin of Species* was, with its challenges to the assumptions of natural theology and biblical literalism of his day, so, too, was the appearance in 1860 of a controversial volume entitled, harmlessly enough, *Essays and Reviews*. Containing contributions by seven English clergymen, the collection is likewise a monument to the serious engagement between religion and science in the Victorian Era. Not only did the essayists respond to Darwin's theory critically (and appreciatively), they introduced Great Britain to methods of interpretation, of *reading* that made biblical studies an equal partner in the advancement of science in the nineteenth century.

Bioethics in Christianity

Edwin C. Hui
Regent College, Vancouver, B.C., Canada

Description

The term “bioethics” was coined in 1927 by Fritz Jahr, who referred to the ethical use of animals and plants in scientific research as a “bioethical imperative.” In 1970, the American biochemist Van Rensselaer Potter broadened the perspective of the term to include solidarity toward the biosphere, with the intention to establish an academic discipline linking biology, ecology, medicine, and human values for the purpose of helping the survival of both human beings and other animal species. Today, bioethics also includes the study of the more commonplace questions of values which arise in different branches of medicine. The difference between “bioethics” and “medical ethics” is vague and

there are plenty of overlaps between the two fields as witnessed by new terms such as “biomedical ethics.”

When “bioethics” first emerged in the 1960s and 1970s in North America, one key issue was human experimentation that exploited vulnerable populations. These experiments were first conducted by German Nazi and Japanese army physicians in Germany and China, respectively, during WWII. The postwar trial of German army doctors led to the famous Nuremberg Code (1947) that has laid the moral cornerstone for ethical human experimentation. Unfortunately, the Nuremberg Code did not prevent the American public from having to face the Tuskegee Syphilis Study, cited as “arguably the most infamous biomedical research study in U.S. history.” The study was conducted between 1932 and 1972 in Tuskegee, Alabama by the US Public Health Service to study the natural progression of untreated syphilis in poor, rural black men. The latter were either not given or prevented from accessing penicillin, even though the effectiveness of the drug for syphilis was established in the 1940s. Other medical and ethical issues that emerged in the 1960s included the use of oral contraceptives, abortion, withdrawing of futile treatments, organ transplants and donations, the definition of death, and allocation of limited medical resources. Given the life-and-death and suffering nature of bioethical discourses, it is not surprising that the persons who first addressed these issues were theologians. As Daniel Callahan, one of the early pioneers of bioethics, remarked: “When I first became interested in bioethics in the mid-1960s, the only resources were theological or those drawn from within the traditions of medicine, themselves heavily shaped by religion” (1990: 2). Hence, although the term “theological bioethics” did not come into usage until later in the development of bioethics, it is no exaggeration to say that “theological” was the distinctive birthmark of “bioethics.” Initially, in the 1960s and 1970s and onward, the theological voices came primarily from Protestant, Catholic, and Jewish scholars; later in the 1990s, Muslim, Buddhist, and Hindu scholars have joined in as well.

One of the earliest and most prominent Christian theological voices in bioethics came from Paul Ramsey (1913–1988). Ramsey was a Methodist and earned his PhD at Yale under H. Richard Niebuhr. He subsequently taught Christian Ethics at Princeton and published his influential book on medical ethics in 1970 entitled *The Patient as Person* in which he exploited several key Christian theological themes, particularly the God-man covenant, creation, human brokenness, and dependence to guide in resolving medical quandaries regarding issues such as resource allocation, abortion, and genetic engineering. Another Christian ethicist of equal importance with Ramsey in his contribution to theological bioethics is James M. Gustafson (1925–), a Reformed theologian who earned his PhD at Yale under H. Richard Niebuhr and held teaching posts at Yale, Chicago, and Emory for a total of 43 years as a theological ethicist. In his seminal work *Can Ethics Be Christian?* (1975a) Gustafson provides an affirmative answer to the question and provides the reason that ethics, including medical ethics, can be Christian because “religion *qualifies* morality” (1975a: 173). This occurs when one’s action and reaction to the other persons is not only influenced by the persons, but also by the sense of an ultimate power that rules and sustains the world. This affirmation enables Gustafson to draw deeply on the Reformed theological tradition to claim that God is related to the world as Creator, Sustainer, Judge, and Redeemer and the implications of these theologies for medical ethics. In *The Contributions of Theology to Medical Ethics* (1975), he specifically makes three theological affirmations: “God intends the well-being of the creation” (1975b: 18); “God is both the ordering power that preserves and sustains the well-being of the creation and the power that creates new possibilities for well-being in events of nature and history” (1975b: 19); and “humans are finite and ‘sinful’ agents whose actions have a large measure of power to determine whether the well-being of the creation is sustained or fulfilled” (1975b: 22).

These pioneering efforts have been followed in the 1980s by other theologians and ethicists,

particularly several Roman Catholics including Richard McCormick, Germain Grisez, and Bernard Haring, and Jewish scholars including Immanuel Jakobovitz and Elliott Dorff. Other younger female theologians have also joined in to provide a voice in feminist bioethics, and they include Lisa Sowle Cahill, Margaret Farley, and Karen Lebacqz. Depending on the different theological traditions they come from, these theological bioethicists use religious languages and symbols as well as scriptural imageries and stories not only when they address audiences within their own faith traditions, but also when they speak in the public square. For example, Cahill insists that justice in access to health care resources, guided by “the priority of the preferential option for the poor,” should be the main focus for Christian theological bioethics, and this includes justice in global access to the goods essential to health. According to this author, justice for the poor and the oppressed is not a mere matter of reflecting a progressive or liberal policy; rather it is fulfilling a goal demanded by the New Testament gospel that should be shared by both left and right wings of the Christian churches. Cahill forcefully argues that theological bioethics must go beyond mere talking to link theology to Christian practices that include involvement in social and political processes and public discourses. Theological bioethics should take the form of “participatory discourse, offering a vision, a voice, and action that can carry into the sphere of democratic activism, both locally and globally” (2005: 6). Since theology reveals the nature of the God Christians believe in: historical, personal, relational, loving and just, theological bioethics must inform a normative bioethical theory that can lead to health care reform that reflects these attributes.

Theological bioethicists have also exerted their influence by participating in the formation of several centers that shape the field of bioethics in the USA, and these include The Institute of Religion at the Texas Medical Center, Houston (1954), the Hastings Center in New York (1961), the Kennedy Institute of Bioethics at Georgetown University (1971), and the Park Ridge Center in Chicago (1985). In addition, they also exert their

influence by serving on important policy bodies such as the US National Commission on the Protection of Human Subjects (1974), President’s Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (1979), the National Bioethics Advisory Commission (1996–2001), and the President’s Council on Bioethics (2001). As a result, theological viewpoints related to bioethical issues are mediated to the public in a variety of ways as these scholars take up different roles in teaching, speaking, writing, and advising.

However, the influence of theological bioethicists has significantly lessened since the 1980s. Instead of speaking in the center stage of the bioethical world, they have become marginalized. There are several reasons for this development. As the discipline of bioethics become more mature in the 1980s, many university philosophy departments set up doctoral programs in bioethics. As a result, a new generation of secular philosophers entered this field of scholarship and many feel that the public debate of bioethical issues should be conducted on more objective, value-neutral, and rational grounds, purged of religious biases and dogmas in order to have more public credibility and viability. Confronted by this objection, and fearful of losing their influence in the public arena, many ethicists with religious commitments decided to change their identity from theological bioethicists to moral philosophers in bioethics. They remain silent about their theological convictions that have hitherto provided rich and substantive discourses on a variety of bioethical issues, opting for a secular and minimalistic approach on these issues in order to win public support. As Leon Kass has observed: “Perhaps for the sake of getting a broader hearing, perhaps not to profane sacred teachings or to preserve a separation between the things of God and the things of Caesar, most religious ethicists enter the public practice of ethics leave their special insights at the door and talk about “deontological vs. consequentialist,” “autonomy vs. paternalism,” justice vs. utility,” just like everybody else” (1990: 6–7). As a result, theology has lost much of its earlier influence by identifying and exposing substantive

social problems due to misuses of medicine and technology, such as profit-driven “managed care,” commercialization of human reproduction, commodification, and trivialization of embryonic life, reproductive surrogacy, genetic screening, and enhancement as a new form of eugenics and so on.

[Islamic bioethics](#)

Description

In contemporary Islam, bioethics is largely perceived as a subfield of Islamic legal reasoning (*fiqh*). As a field, it developed since the 1970s and 1980s following the introduction of groundbreaking medical technologies in reproductive medicine and end-of-life care. Therefore, bioethics developed primarily as medical ethics. Only during the 1990s and especially after 2000, the discussions switched to more general topics with less direct links to practical medical care, particularly due to the remarkable breakthroughs in the field of genetics.

Since bioethical questions are usually approached within the framework of *fiqh*, Islamic bioethical reasoning is qua definition perceived as a religious act. So far, no distinct subdiscipline “Islamic bioethics” has developed on a general level. There are several notable religious scholars who have specialized in bioethical questions since the 1980s, but the implementation of teaching programs is making only slow progress since 2000 in a handful of Muslim majority countries such as Iran, Pakistan, and Saudi Arabia.

Islamic bioethicists aim to show that the ethical-legal system of *fiqh*, which has its main roots in the time span of the seventh until the eleventh centuries C.E. and developed further until nowadays, is able to contribute answers to the rapid developments of modern medicine and biotechnology. For this reason, their interest in the relation between science and religion is largely guided by theology, i.e., they assume and often aim at proving that contemporary scientific discoveries only uncover the rules of God’s creation and can easily be brought into accordance with verses from the Qur’an or the collected deeds and sayings of the Prophet Muhammad and his companions (*Sunna*). This would proof scientifically the heavenly origin of the Qur’anic message and the godly authorization of Muhammad’s prophethood, because both Qur’an and *Sunna* from the seventh century would already contain knowledge uncovered by modern science only in the twentieth and twenty-first centuries.

Besides, Qur’an and *Sunna* texts from a great variety of authors from the four legal schools of

Sunni Islam and the *fiqh* tradition of the Shiites command authority in Islamic bioethical discussions due to a consensus about these sources' authoritativeness which developed over the centuries. Muslim scholars from the history of science or medicine are quoted much more rarely and usually in passing.

During the history of *fiqh*, the concept was developed that Islamic law serves five fundamental values: the protection of religion, human life, offspring, property, and intellect, respectively. In Islamic bioethical debates, the protection of life and offspring receive most attention. The main principles in achieving the protection of these values are several forms of balancing legally protected interests (sg. *maslaha*). In addition, legal maxims such as "necessity makes the forbidden allowed" (*al-darura tubih al-mahzûrât*) provide the possibility of exceptional rulings. Generally speaking, biotechnological and medical innovations are considered unproblematic, because it is argued that they cannot infringe on God's creational will otherwise the created mankind would not have been capable of such innovations. They are only viewed as forbidden or reprehensible if they collide with a religious rule directly or indirectly. However, exceptional rulings are allowed within the framework of balancing legally protected interests.

Nature and everything created apart from humans are explicitly said to serve the purpose of attending mankind, which is thus entitled to make use of it to enhance its life quality. Humans are conceptionalized as the only being with a mixture of earthly and heavenly components (the body and the soul). Therefore, they constitute a linkage between this world and the next, which elevates them over the rest of God's creation. Life is considered to begin with the mixing of egg and sperm, although there is considerable and yet undecided debate about the ontological status of nidation. The majority of Muslim bioethicists follow the model of increasing protection rights in the course of embryological development, granting full protection rights only after the 120th day of pregnancy, commonly perceived to be the date of ensoulment. Consciousness and reason are situated in the soul. Since the 1970s,

the traditional concept of heart-lung death has been substituted by the brain death criterion. A supranatural reality is assumed to exist, meaning not only God but also angels and especially a sort of demons (*djinn*s). Therefore, mysteries are a break with the usual order of things due to God's will. Mankind's ability of knowledge is generally seen as limited and depending on God's will. Truth can only be found through the interpretation of the foundational texts of Islam, but differing perceptions because differences in time and space are accepted as an intrinsic element of *fiqh*.

Related Terms

[Bioethics and the Jewish culture](#); [Jewish bioethics](#)

Jewish bioethics deals with major moral, religious, and legal issues for communal forms

of Judaism in modern medicine. Each issue is described biologically and medically, related to issues in traditional rabbinic law, and then discussed by reference to leading contemporary rabbis in different contemporary Jewish religious movements, notably Orthodox, Reform, and Conservative (noting differences between the seven main groups of communal Jewish life – the Ashkenazi, Roman, North African, Kurdish, Near Eastern, Yemenite, and Ethiopian – as well as some numerically significant minorities – the Lemba of North Africa, the B'nai Menashe of India, and the Crypto Jews of South America).

The discussion of bioethics is guided at the most universal level by four general principles of western ethics and eight general principles of Jewish ethics. The western principles are (1) Maximize freedom of patient choice (Autonomy), (2) Cause no injury to the patient (Nonmaleficence), (3) Promote patient welfare (Beneficence), and (4) Distribute benefits in a just manner (Justice). The rabbinic principles are (1) Be fruitful and multiply (with reference to Gen 1:2), (2) Be concerned for the suffering of animals, (3) Repair the world (tikkun olam), (4) Do not destroy (with reference to Dt 20:19), (5) Preserve life, (6) Heal (with reference to Ex 21:19), (7) Act according to the natural way, and (8) There is nothing new under the sun (with reference to Eccl 1:9).

What emerges are positions on the issues that will be familiar to any student of bioethics (from the application of the four general principles) but will be seen in distinctively new perspectives (from the application of the eight rabbinic principles). Issues commonly discussed include (1) methods to correct infertility, male and female, (2) responsibility toward all stages of preembryos, from stem cells to 40 days after fertilization, (3) cloning, (4) designer genes and children, (5) the special case of human engineering in order to avoid the eight deadly genetic diseases especially prevalent among Jews of eastern European descent – Canavan disease, Huntington disease, cystic fibrosis, Niemann-Pick disease, Gaucher disease, fanconi anemia, Bloom Syndrome, and familial dysautonomia,

(6) in order to select sex, (7) in order to test for specifically marked Jewish genes, and (8) in order to study both the genealogy of individuals and the collective history of the Jewish people, (9) morally judging genes in general, and finally (10) using genetics to make naturally non-kosher food kosher.

Multiple moral recommendations emerge, not all of which are complementary with each other. It is not surprising to see that many of the differences between liberal and conservative rabbis on questions of medical and biological ethics correlate, especially in North America, with differences between different kinds of Christians, liberal and conservative. However, some of the answers are surprising and do not correlate to general social class and political identities in American and European society. Moral judgments about cloning are a dramatic example of differences between Jewish and Christian moral political stances in western society. In general, traditional rabbinic authorities tend to allow cloning while more liberal authorities oppose it. Similarly, the logic of Jewish law is such that traditional Jews tend to prefer non-Jewish sperm donors while liberal Jews tend to prefer Jewish donors. The principle underlying the first anomaly is the extraordinary pressure following the Holocaust to parent Jews (viz., be fruitful and multiply), and the principle underlying the second anomaly is the extreme negative value placed on any form of incest (viz., act naturally).

[Computational biology](#)

Description

The field of Bioinformatics is an area of study that involves several fields, including computer science, molecular biology, genetics, and statistics. Bioinformatics is devoted to the development of theoretical and computational models and technologies for the solution of problems based on molecular data. In general, it involves the use of information technologies for the management of biological and genetic information, namely, to collect, store, analyze, and integrate data.

The main goals of Bioinformatics are (1) to manage data in such a way that it allows easy access to the existing information and to submit new entries as they are produced; (2) to develop technological tools that help analyze biological data; and (3) to use these tools to

analyze the data and interpret the results from a biological perspective.

The development of Bioinformatics goes back as far as 1948, to the Ph.D. thesis by Dr. Margaret Oakley Dayhoff on the use of computers in chemistry and biology. She used her knowledge of chemistry, mathematics, biology, and computer science to develop an entirely new field. However, the release of the first draft of the Human Genome Project in 2001 was one of the main events that generated a good deal of attention from scientists from different fields. Therefore, in the last two decades, we have witnessed a significant increase of available online tools and services, such as databases, applications to analyze biological and genetic data, gene ontologies, and paper repositories. Several technologies to support research at the laboratories have also been developed. Among the main data repositories are GenBank repository of nucleic acid sequences (<http://www.ncbi.nlm.nih.gov/Genbank/>), the SWISS-PROT database of protein sequences, and DNA Data Bank of Japan, DDBJ (<http://www.ddbj.nig.ac.jp/>).

Self-identification

Science

Bioinformatics is not a science itself. It may be considered as a scientific and technological interdisciplinary endeavor, since it involves theoretical and applied aspects of several sciences and technologies. It integrates work from biology, computer science, mathematics, statistics, genetics, medicine, and chemistry.

Characteristics

One aspect that makes this discipline distinctive is the fact that it integrates several sciences and disciplines. Bioinformatics is mainly concerned with understanding living beings and their internal processes during their lifetime and how genetic information is transferred throughout generations, and their interactions with the environment. It involves

the development and use of technological resources that contribute to the solution of health problems and to some extent understanding genetically related problems.

Relevance to Science and Religion

Bioinformatics studies biological systems, models biological elements, and processes from a scientific point of view. It also deals with the development of technological tools using information and telecommunication resources to support research processes in biology, genetics, and chemistry. A significant amount of research in Bioinformatics involves genetic information and assumes concepts supported on evolutionary theory; it attempts to give scientific explanations to some of the same main issues that Religion deals with such as the origin of life and the evolution of living beings.

Sources of Authority

Although there are several institutions that may be considered as the main authorities that are concerned with particular subareas of Bioinformatics, the following organizations can be considered as the well-recognized worldwide authorities in Bioinformatics:

- The European Molecular Biology Laboratory, EMBL (<http://www.embl.org/>)
- The National Institute of Health, NIH, from the United States Department of Health and Human Services (<http://www.nih.gov/>)
- National Institute of Genetics of Japan, NIG (<http://www.nig.ac.jp/index-e.html>)
- The National center for Biotechnology Information, NCBI (<http://www.ncbi.nlm.nih.gov/>)

Ethical Principles

This discipline deals with the study of living beings, and in many cases with testing new medical developments on animals and even on human beings. Therefore, its ethical principles are the general principles from biological and medical sciences.

Key Values

The key value of Bioinformatics is the study of living beings to provide explanations to diverse biological phenomena and solutions to health problems that can improve the quality of life in humankind.

Conceptualization

Nature/World

Nature is conceptualized as the constituent physical and biological elements that form the universe. *World* is the set of all physical elements in the universe.

Human Being

A human being is considered as a complex biological being endowed with special features that make him/her very efficient at problem solving and for understanding and changing his/her environment for his/her benefit and those of their own species.

Life and Death

Life is conceptualized as the presence of special functions in biological systems that allow them to remain in its environment performing its primary functions. Death is the event that happens when a living organism is not capable of continuing to perform its basic functions.

Reality

Reality is considered as the set of all elements in the universe that exist and can affect and interact with each other.

Knowledge

Knowledge is a set of data, rules, and facts known about a particular system or process.

Truth

Truth is some factual knowledge about the world that can be verified.

Perception

Perception is some partial knowledge that any life form or artificial being acquires from its

environment through some special components provided for such a task.

Time

Time is a reference measure that is used to keep track of the changes that occur in the world.

Consciousness

Consciousness is a life form or organism's ability to know about itself and its role in the world and of being aware of the consequences of its actions.

Rationality/Reason

Rationality is an ability of human beings to analyze situations and make what they believe are the right decisions under those circumstances.

Mystery

A mystery is something for which there is no formal or scientific explanation.

Description

Anthropology means the study of human beings. In the early years of anthropology in the

*Jay R. Feierman has retired from University of New Mexico

nineteenth century and first half of the twentieth century, the discipline was divided into cultural anthropology and physical anthropology. Cultural anthropologists studied features that were transmitted across generations by social learning and which constituted what anthropologists considered culture. These features could be material objects, such as tools, or they could be the structural design features in describable patterns of behavior that were observable in living societies. In addition, cultural anthropologists often interpreted that which had been transmitted across generations culturally within religion, as by Clifford Geertz or structural anthropologists, such as Levy Strauss. In contrast, during this same time period, physical anthropologists were primarily interested in the comparative study of bones. They compared the bones of hominoid and hominid ancestors to modern human bones in attempts to reconstruct the evolutionary history of the human species.

In the latter half of the twentieth century, a small number of anthropologists began to study human behavior as well as human culture using Darwinian evolutionary theory. This new approach broke down the previous dichotomy of anthropology into cultural and physical and created a new more encompassing category called biological anthropology (Standford et al. 2008). Within biological anthropology, there are many more subdivisions, such as biosocial anthropology, anthropological genetics, and anthropological behavioral ecology. What these new approaches have in common was that they all use Darwinian principles of evolution by natural selection to study what used to be separate domains of cultural and physical anthropology. The most surprising application of Darwinian theory has been to cultural anthropology (Boyd and Richerson 1985).

Parallel to the introduction of Darwinian evolutionary theory into anthropology in the second half of twentieth century was the extension of Darwinian evolutionary theory from the biological study of the behavior of nonhuman animals to the study of the behavior of human beings. The branch of biology that was studying behavior of animals in their natural habitats was called

ethology. Human ethology is a subdiscipline of ethology. Ethologists, whether they study nonhuman species or humans, usually ask one or more of the four questions about behavior originally proposed by one of ethology's founders, Nobel Laureate Niko Tinbergen: What is the behavior's evolutionary history (phylogeny)? What is the behavior's development in the lifespan of the individual (ontogeny)? What are the behavior's proximate, mechanistic causes? Does the behavior increase one's survival or have adaptiveness? Many ethologists use Niko Tinbergen's definition of behavior, which is "the total of movements made by the intact animal" (Tinbergen 1951). However, other definitions of behavior used by ethologists and human ethologists are broader than movements. Synonyms for ethology are the biology of behavior and the comparative study of behavior. Even though human ethology emerged from biology rather than from anthropology, they both share an interest in understanding human behavior from a biological and evolutionary perspective.

Ethology can also be divided into behavioral ethology, cognitive ethology, and neuroethology. Behavioral ethology's emphasis is on the movements themselves, often in conjunction with trying to determine the intra- as well as extra-individual proximate causes of the movements. Cognitive ethology's emphases are the proximate cognitive functions as well as the evolution of the neural structures whose proximate functions they are. Cognitive proximate functions include such things as thinking, desiring, planning, goals, etc. Neuroethology's emphasis is on neurophysiological, proximate, and causal mechanisms of naturally occurring behaviors.

Ethology emerged out of zoology and the naturalistic study of animal behavior at the end of the nineteenth century (Burkhardt 2005). By the early to mid-twentieth century, ethology began developing a terminology, methods, and eventually theoretical formulations with which to scientifically study and understand the behaviors of animals in their natural environments (Immelmann and Beer 1989). Today, ethological methods (more so than ethological theory) are commonly used when the behavior of animals is

studied in their natural or seminatural environments. Ethological methods have been adopted by individuals who now call themselves animal behaviorists, sociobiologists, biosocial anthropologists, comparative and evolutionary psychologists, primatologists, behavioral ecologists, and human ethologists.

In the latter half of the twentieth century a few ethologists began applying the methods and theory of animal ethology to the study of human beings (Eibl-Eibesfeldt 1989). One of the most recent developments in human ethology has been its application to the understanding of human religious behavior (Feierman 2009). When religious behavior is the focus of ethological study, other aspects of religion – moods, feelings, beliefs, and values, the essence of religious experience – become contributing causes of the behavior. In addition, questions about religious behavior's evolutionary history, development in the lifespan of the individual, its proximate, mechanistic causes, and does the behavior have adaptiveness, can all be asked. Ethological studies of religion are very narrow in scope. They are not going to answer the big questions about religion. They have to be considered adjuncts and complements to other ways in which the fullness of religion is studied and understood. However, within this narrow confine, there are aspects of religion which ethology may be uniquely qualified to address.

Self-identification

Scientific disciplines usually start out, if possible, with an observation and description phase, followed by a categorization of that which has been observed and described into smaller units that become the units of specific study. To guide the study, theoretical propositions, which deductively predict outcomes of either spontaneous acts of nature (including specific naturally occurring behaviors) or of specific experiments done in the field or the laboratory, are formulated. Ethology was developed out of the observations of animals in their natural settings by late nineteenth-century naturalists. As a result, ethology already had

a good observational foundation of the behavior of animals by the time more formally trained zoologists started to systematize their observational methods in the early twentieth century.

In the first half of the twentieth century, ethology – primarily under the guidance of Konrad Lorenz, Niko Tinbergen, and Karl von Frisch – developed an inductive approach by careful observation of individual organisms alone, in pairs, or in groups of a relatively few species, predominantly birds, fish, and insects (bees). Only after a number of years of observation and inductive research did the founders of ethology generate theoretical propositions by which instinctive behaviors of animals could be understood and which outcomes could be predicted. In a move away from the early twentieth-century “instinct theories” of Harvard Psychology Professor William McDougal, the early ethologists conceptualized instincts as coordinated motor pattern behaviors. These theoretical propositions then addressed the proximate, causal mechanisms for certain types of these stereotyped instinctive behaviors, which are seen in all vertebrates, including humans. Prior to this time and based on the ways of conceptualizing behaviors of McDougal, so-called instinctive behaviors were thought to be outside the realm of scientific understanding. In 1973, the Nobel Prize in Medicine and Physiology was given to three ethologists – Konrad Lorenz, Niko Tinbergen, and Karl von Frisch – for their discoveries of how to understand animal instincts.

In the latter half of the twentieth century, a few individuals began applying ethological theory and methods – as worked out primarily on fish, birds, and insects – to the study of humans. Much of this early work involved observation (often with the use of documenting film), description, and applying the theory of instinct, developed in the lower animals by the early ethologists, to some of the more basic human behaviors – courtship, mother–infant interactions, children playing behavior, etc. Much of human ethology's current methodology is still inductive. Because of the strong observational methods used in human ethology and because the main topic of study is

behavior, which is observable, human ethology can be said to be in the late descriptive phase in its development as a science, still struggling to discover theoretical propositions with which to understand the more complex and variable behaviors of human beings beyond the simple, coordinated motor patterns and reflexes. Much human behavior appears to be outside of the realm of understanding by current human ethological methods and theory.

Characteristics

In comparison to the other biological disciplines, ethology is distinctive in that behavior (the movement of an individual) is always the object of study, even if the particular study is asking one of Tinbergen's four questions about behavior. There is overlap of ethology with a number of other disciplines, although ethology is distinctive in a number of ways. The emphasis in behavioral ethology is on observing movements directly. This is in contrast to what people say about how they behave or would behave or how they answer questionnaires on how they behave.

Other disciplines that include behavior in their area of study often make the actual movement of the individual an ancillary item or do not study it at all. Sociobiology, which can be considered the deductive sister discipline of the more inductive discipline of ethology, starts out with a theoretical proposition generated from some aspect of evolutionary theory and then predicts the behavior of individual organisms. Ethology more often starts out with the behavior of a single organism, dyads, or groups of organisms in a particular species and then sees the degree to which the principles governing the behavior are species-specific or illustrative of a more general principle that extends over a wider taxa. That methodology has been criticized.

Because human ethology developed out of nonhuman animal ethology, primarily fish, birds, and bees, human ethologists have at times been rightly accused by other disciplines that study human behavior of studying humans as though they did not talk. There has been much

more emphasis on understanding "body language" in humans ethologically than vocalized or written symbolic language.

Cognitive ethology is distinct from cognitive psychology and cognitive science in terms of the emphasis on cognitive phenomenon as seen in natural environments. The same applies to neuroethology as compared to neuroscience in general. In neuroethology, the emphasis is on the proximate, neurophysiological causes of behavior in natural environments. To date, most neuroethology has been on simpler organisms. However, with functional brain imaging, at least some type of neuroethology of humans is now possible.

Relevance to Science and Religion

Human ethology is definitely a newcomer to the scientific study of religion when compared to other scientific disciplines. Although in the 1970s and 1980s, there were comments about religious behavior from some of ethology's sister disciplines, such as sociobiology, biosocial anthropology, and behavioral ecology, an early book about religion by someone who is an ethologist was *Why God's Persist: A Scientific Approach to Religion*, published in 1999 and written by Robert A. Hinde (1999). In the past 10 years, there have been a number of edited books about the evolution of religion that have contained a few chapters that can be considered ethological, at least in method, and where behavior was the object of study (Volland and Schiefenhover 2009). Human ethology during the 1970s and 1980s was primarily interested in other aspects of human behavior, such as courtship, children's play behavior, agonistic behavior, dominance relations, and political behavior. During this same period of time – the late 1980s to present – a new academic discipline called evolutionary psychology was emerging. Many of the individuals who had been attracted to human ethology in the 1970s and 1980s found themselves more drawn to evolutionary psychology where the emphasis was less on behavior per se and more on the "ultimate functions" or

adaptiveness of behavior. At the same time, the main journal publishing human ethology studies changed its name from *Ethology and Sociobiology* to *Evolution and Human Behavior*, reflecting the growing influence of evolutionary psychology and the waning influence of human ethology on the evolutionary and biological approaches to studying and understanding human behavior.

Human ethologists organized themselves into The International Society for Human Ethology (ISHE) in the 1970s. This small society, which has somewhat over 200 members, has met biennially to the present. It also publishes the *Human Ethology Bulletin* (ISSN 0739-2036). At the 19th biennial meeting of the society at the University of Bologna in 2008, a symposium was held on “The Biology of Religious Behavior: A Human Ethological Perspective on Religion.” That was the first time that the society targeted religion as an object of study. There were 12 papers on the biology of religious behavior given within the symposium. That symposium inspired the book of a similar name Feerman (2009).

Human ethology’s relevance in the science religious dialogue is that ethology in general and human ethology in particular tend to concentrate on that which is observable as the object of study. As such, the ethological study of religion concentrates on the observable aspects of religion that can be studied in a scientific way. This type of understanding can aid in understanding some of the ways at the biobehavioral level that different religions are similar. This similarity across religions can aid in bridging the religious divide as well as in coping with religion’s excess, as in fanaticism.

Sources of Authority

As a science, the sources of authority are those authors whose work has been peer reviewed and published and who have had the most influence on other people in the field. The most influential sources of authority in ethology are its founders Konrad Lorenz (1903–1999), Niko Tinbergen (1907–1988), and, to a lesser extent, Karl von Frisch (1886–1982). All three men won the

Nobel Prize in Physiology and Medicine in 1973 for their paradigm-changing work as ethologists.

There are of course many individuals who preceded them whose names are all but forgotten by people who today consider themselves ethologists. Such names include Charles Otis Whitman, Oskar Heinroth, George Romanes, and others. Both Konrad Lorenz and Niko Tinbergen had students who studied under them and who also became influential in the field. In the 1970s and 1980s, the two most influential students in terms of their impact on human ethology were Desmond Morris, a student of Niko Tinbergen, and Irenäus Eibl-Eibesfeldt, a student of Konrad Lorenz. Morris published a number of general readership books, such as *Manwatching*, on the application of ethology to human behavior. Eibl-Eibesfeldt is known best for his 1989 book, *Human Ethology*.

Another individual whose work is clearly human ethology, but who is not really identified by that name, is Paul Ekman, Professor of Psychology in the Department of Psychiatry at The University of California, San Francisco. His work on the emotions, especially in the face, has had wide influence in many different fields.

There are a small number of “F2 generation” academic descendents of the Nobel Prize generation, whose work today is continuing human ethology. In addition, there are a number of other individuals who were not direct academic descendents of the three Nobel Prize winners in human ethology but who have had a major impact on the field. Michael T. McGuire, Professor Emeritus at UCLA and founding Editor in Chief of the journal *Ethology and Sociobiology*, is one such individual. Some other influential people in human ethology include William Charlesworth, the late Daniel G. Freedman, and Robert A. Hinde. Today, there are a few young people still being attracted to the field of human ethology, many of whom are from eastern Europe. However, the influence of the discipline of human ethology both in influencing how human behavior is conceptualized and in attracting new students to the field peaked in the 1970s and 1980s.

Ethical Principles

As a scientific discipline, human ethology subscribes to the basic ethical principles that guide all science. These principles include empiricism, objectivity, and openness to all research-supported assertions, critical thinking, and respect for all people, the environment, and animal life.

Because human ethology often observes and sometimes films or videotapes the behavior of human beings in naturalistic settings, informed consent is an ethical issue. However, it is not an issue that is much discussed. The general consensus appears to be that behavior in public places can be filmed or videotaped, even without explicit consent. Exceptions might be where the behavior is out of the ordinary, would embarrass or be otherwise detrimental to the person being videotaped, or might reveal personal information not intended to be public by the behaving individual.

Many of the early human ethology films were made by Irenäus Eibl-Eibesfeldt on a number of tribal societies. These films are currently being archived in Vienna, Austria. The technique to film unstaged, naturalistic behaviors, often in tribal villages, was the use of a mirror lens. This was a telephoto-looking lens that had a mirror prism in it which actually captured images at a 90° angle from where the front of the lens was pointing.

There is nothing in the official constitution of the International Society of Human Ethology, the Bulletin, or on the society's web site that addresses ethical principles of the discipline. Ethical behavior was however a topic that was addressed from an ethological perspective in general, such as how did it evolve. It was not addressed as it pertains to work done by human ethologists.

Key Values

If values are the rank order of different beliefs within a value system, human ethology has the following key values. The proper study of human behavior is human behavior itself, not what

people say about their behavior. The proper place to study human behavior is in a naturalistic setting that comes close to the type of setting in which such behavior would have evolved or is currently a setting in which the behavior is occurring. This is often called a naturalistic or seminaturalistic environment. In addition, there are some core values of all ethologists, such as separating the form or structure of a behavior from the proximate function of the behavior.

Conceptualization

Nature/World

Nature is the environment in which humans find themselves and to which their structures adapt. Whereas the current environment is not the same as the ancestral environment in which many human adaptations developed, the current environment would still be considered "nature" for modern human beings. The world is synonymous with the planet earth. Nature for human beings is that part of the planet earth which humans inhabit.

Human Being

A human being is defined as a member of the species *Homo sapiens*. Ethologists conceptualize human beings as having evolved from hominid-like ancestors over the past several million years as the result of Darwinian natural selection. Our closest living relatives would be the chimpanzee and bonobo, which are great apes from which we diverged approximately 6 million years ago. Human beings are distinguished by their cognitive capacities that include their intelligence and their use of symbolic language and reasoning. Human beings also have a degree of self-awareness and self-consciousness that allow for reasoning about their own being and behavior, which allow for moral capacities not possible in lower forms of life.

Life and Death

Ethology, as a life science, sees life as combinations of organic and inorganic elements capable of replicating and adapting to changing

environments with changes in the structures of the organism through natural selection. The origin of life is of course unknown. However, ethologists presume that the transformation from nonliving to living matter occurred by natural, rather than supernatural, means. Death of an individual is conceptualized as the termination of life. Death is inevitable for individual organisms. The organism that is dead is no longer capable of self-maintenance. The elements of the organism return to the earth from which it sprang. Most ethologists would subscribe to the concept that human beings are “carriers” of the DNA that made us and that evolution and natural selection is adapting DNA to changing environments, which is accomplished by various mechanisms including new species formation. Human beings are such a species and a relatively new one at that. Human ethology does not take a position on life after death or a continuation of consciousness after death.

Reality

Reality is conceptualized as the extra-individual environment to which the organism, in this case the human species, adapts. The perception of the individual, by which subjective reality is known, is not considered the same as reality, as each species only perceives those aspects of reality that are required to foster the survival of the species in a natural environment. As such, absolute reality is unknowable from an ethological perspective.

Knowledge

Is the adaptive application of information (that which is necessary to make decisions). Adaptive means that the information is applied in a way that fosters reproductive success or survival of the bearer (or the bearer’s kin) of the knowledge. The theoretical basis for human ethology is critical realism. The presumption is that every adaptation in an organism reflects a fitness-improving feature to reality outside of the organism.

Truth

Truth is what is. Science in general and human ethology in particular cannot determine what is true, only what is not true. In some way, if the

parameters can be defined, truth is what is left when what is not true is eliminated. Human ethologists can study humans as they attempt to determine what is true. However, in the process of natural selection, what is contributory to survival and reproductive success is more important than what is true. As a result, humans harbor many beliefs (that which is held to be true), which may not be true. Many of these beliefs have to do with religion and politics.

Perception

The adaptive modification of sensory information so that it is potentially actionable. Within cognitive ethology, the issue of subjective perception is an issue. For the behaviorist branch of ethology, perception can be determined experimentally as those features of a stimulus which are required to get a specific response. Often, only certain features of a stimulus are attended to and therefore needed.

Time

The directional interval between behaviors (movements) that are not done simultaneously or the interval between the repetition of the same behavior, as measured in standard units, such as seconds, hours, days, etc. Ethology only deals with time at a proximate and practical level. It does not address the bigger issues in terms of the relationship between time, space, gravity, etc., that physicists contemplate.

Consciousness

An awareness of one’s awareness, where awareness is defined as the ability of a stimulus to cause a change in behavior. A conscious individual is aware that specific stimuli are causing a change in behavior. Organisms can be aware but not conscious, but all organisms that are conscious are also aware. Consciousness also allows for an awareness of self, but awareness of self is not a requirement of consciousness. Most ethologists presume that humans are not the only species that has consciousness, as it may be present in all birds and mammals. However, based on experimentation, only some taxa like the great apes and perhaps some sea mammals may have an awareness of self as part of their consciousness.

Rationality/Reason

Rationality is the adaptive, cognitive processing of information by evolved algorithms. Cognitions reconstruct the structures of reality outside the subject from sensory impressions perceived as projections of these structures. The capacity for *a posteriori* and *a priori* reasoning is thought to have evolved by Darwinian natural selection. Konrad Lorenz's *Behind the Mirror* (Lorenz 1977) is a treatise on how *a priori* reasoning could have evolved by natural selection. The main difference between *a priori* and *a posteriori* reasoning is that in *a priori* reasoning, the objects of reasoning are symbols with attributed meaning, rather than objects in the natural environment.

Mystery

Mystery would be anything that is not known within the realm of scientific certainty. As such, much of nature and the world and the laws that govern them are still mysteries.

Relevant Themes

Additional issues and themes that are relevant for human ethology, put in the form of questions, are as follows:

1. What are the proximate mechanisms by which religion has such a powerful influence on human behavior?
2. What are the actual biological factors and mechanisms that make being religious the default position for most human beings?
3. Is there a critical period for the acquisition of religion, like the critical period thought to be necessary for the acquisition of language?
4. What are the mechanisms of faith by which humans believe things that are counterfactual and counterintuitive?
5. What are the mechanisms of subjective religious experience?

Ethology, in conjunction with other biobehavioral sciences, has the capacity to answer all of these questions. However, whether these questions will be answered will depend on the priority that ethologists and other biobehavioral scientists

give to these types of questions. Religion must compete with other areas of human life for the attention of the biobehavioral scientists who study these types of questions. However, given the fact that religious differences now are dangerously dividing the world, perhaps more ethologists and other biobehavioral scientists will turn their attention toward religion.

Biological Evolution

► Evolution, Convergent

Biological Hierarchies

Stanley N. Salthe

Department of Biological Sciences, Binghamton University, Binghamton, NY, USA

Biologists have in the course of their activities constructed two kinds of hierarchies, which have different logical bases (Salthe 2002, 2012). Before getting into details about these, consider a very commonly acknowledged example of ► **hierarchy** – the organization of an institution like the army. Here we have, in simplified form, a general (in corporations, it would be a CEO), who controls several staff officers, who in turn each control several officers of lower rank, who each control many soldiers. A diagram of this would show lines of command from the general at the top branching downward as an upside-down tree. There are two kinds of hierarchies involved in the relations here.

On the one hand, we can see that the social role of a general, his sphere of interest and influence, is geographically much greater – for example, an entire battlefield – than that of any of his subordinates, while a soldier at the bottom of the hierarchy would be concerned only with the immediate surroundings of his own current position. So the social role of a general actually encompasses that of a soldier, whose social role is contained within it, even though the soldier's body is not contained within the general's body. The logic of this “structural command hierarchy” is that of a *compositional hierarchy* (Ahl and Allen 1996; Morrison and Morrison 1982; Salthe 1985; Weiss 1971). The general's social role encompasses those of his subordinates.

On the other hand, we can examine the trajectory of a particular command. The general might deliver his order that the army should next carry

out some maneuvers to surround enemy forces as soon as possible. A staff officer will translate this into a more particular order, supplying, for example, a date and time when this should be carried out. A lower ranking officer will then further modify this into directions that take into account the particular terrain his group is confronting. And so the general's order is gradually refined, being made more particular with much greater detail added along the way. The logic of this flow of command is that of a *subsumptive hierarchy* (Polanyi 1968; Sabelli 2005; Salthe 2012). The general's order subsumes those of his subordinates.

Turning now to biology, beginning with Linnaeus in the eighteenth century, the discipline of biological systematics (Schuh 2000), which is concerned with determining genealogical relationships among the many different species in the world, has been constructing a “tree of life.” This form, which is that of a subsumptive hierarchy, looks like the tree in the structural command hierarchy discussed above, but its meaning is very different. At the base of this tree is represented the oldest ancestral taxon. Branching from this are waves of descendant taxa gradually approaching contemporary, living ones at the tips of the branches. In evolutionary biology, this picture represents the evolutionary generation of new taxa from ancestral ones, as genetic information (like a command) is passed on from extinct species to more recent ones. The latter carry an increasing amount of information generated by various kinds of mutations along the way. And so the tree of life could be thought of as being connected by way of genetic information. The older genetic information subsumes any current information, which was gradually built up from it. Of course, many taxa become extinct along the way, and so any portion of a genealogical tree does not necessarily keep adding branches, thereby growing in span (The number of lowest level entities that are parts of, or subsumed by, the apex, or base, of a hierarchy, given some number of levels). For example, the genealogical tree of hominid primates, culminating at present in humans, has lost branches more recently rather than gaining them, leaving only us.

Biologists, beginning in the nineteenth century, realized that larger than microscopic living things, like plants and animals, are materially composed of smaller units – biological cells – and also that the plants and animals themselves in turn do not live their lives alone. Rather, living things necessarily belong to local groups of interbreeding individuals referred to as demes (which would form a genealogical tree within a species). At the same time, ecologists realized that organisms exist in more or less socially organized groups – biological populations, making up local flocks, troops, schools, etc., in animals, and stands in plants. These interact with other such groups in a ► [biome](#) by way of passing energy from one species' population to others. (Deme and population are frequently, but not always, the same group.) So we have populations/demes composed of organisms which are composed of cells, all connected by energy transformations, together forming compositional hierarchies.

We can discern in the biological applications of the two kinds of hierarchy two ways of looking at the world – as a realm of energy transformations, or as a framework for passing along accumulated information.

Using the compositional hierarchy, animals, for example, can be seen to marshal energy resources in order to react to some event. This involves energy expenditures in the brain, the nervous system, and in muscles. In their cells, we find that this is most often based on the conversion of the chemical ► [ATP](#) to ADP and Pi (inorganic phosphate), a chemical reaction that releases free energy that can be used by a cell. Cells act in unison as groups in a tissue (muscle) or organ (brain), which then produces the animal's motion. This motion might result in the capture of some food, some of which gets assimilated into the body by other cells, resulting in ATP being regenerated from ADP and Pi by capturing energy from a chain of chemical reactions involved in the breakdown of the food. Plants, on the other hand, will have deployed their leaves, mostly by way of growth, so as to optimize their ability to capture some of the energy of sunlight by way of photosynthesis in

the leaf cells. This is captured in the form of manufactured sugars, which can be carried throughout the plant by way of its circulatory system. Since the energy in both cases is chemical, and so microscopic in amount, we can see that it would be impossible to understand the lives of plants and animals without taking into consideration the fact that they are structured as compositional hierarchies. All biological energy expenditure is microscopic, and so only cooperative activity by many cells wherein this happens allows these microscopic energies to be marshaled for macroscopic activity and growth.

Concerning the informational relations in biology, we understand that genetic information has been passed on through many millions of generations since the origin of the genetic system. Many genes have been preserved by repeatedly being copied over very long periods of time, so that some of ours are not very different from those found in insects. But many new regulatory genes have been added in the different lineages of living things. Since it is reproductive activity in demes that results in passing genes on to new generations and species, the question arises as to how to represent a *genealogical hierarchy*. We can use the formal property of a compositional hierarchy – [higher level, larger scale [lower level, smaller scale]] – to form the following hierarchy:

[lineage[biological species[deme[family
[individual organism]]]]]

These are all entities that can be said to hold genetic information. A biological species, for example, would contain all the information held in its many demes. This may be compared with a similarly constructed *ecological hierarchy* in the same compositional hierarchy format.

[biogeographic region[biome[population
[flock, troop, etc.[individual organism]]]]]

In this case, these are all entities that could be held to engage in energy transactions that are informed by the genetic information held within organisms, and that are actually carried out by those organisms.

Note that these hierarchies have the form of trees branching to the right, and so in these representations there would be many organisms in any troop or family, fewer families and troops within a deme or population, still fewer demes and populations with a species or biome, even fewer species and biomes contained in only one lineage or biogeographic region. Note that the ecological hierarchy is made of actual material objects, while the genealogical hierarchy is composed of relationships.

From the point of view of the subsumptive hierarchy, these relationships would be represented as:

```
{kingdom{order{family{genus
    {species{subspecies}}}}}}
```

This would represent one branch of many in the tree of life or Linnaean hierarchy. There could be branching at each level here; thus, for example, one genus might hold many species in its span. The genes used for coding proteins might be almost the same in all the levels, but increasing numbers of regulatory genes would be found in the subordinate taxa. Only the genetic information that is identical in all the contained subspecies would be considered to be held in the species in question, and only the genetic information found in all the species would be considered to belong to the genus in question, and so on. As with a command, genetic information gradually becomes more particular as it is imagined in each succeeding level. This shows that these standard taxa of biological systematics are classificatory categories, not actual material entities.

Description

Biological psychology can be concisely defined as the scientific study of the biological processes underlying or influencing mind and behavior. In this regard, it is basically a materialistic approach to the human condition since it provides methods and strategies to investigate the natural causes

and aims of (human) behavior. It is one of the few scientific disciplines at the crossroad between humanities and natural sciences. Dewsbury (Dewsbury 1991) argued that the synonym *psychobiology* was probably coined at the beginning of the twentieth century, but some authors have dated its first use many years earlier. Some students of *biological psychology* may have used this term or its synonyms to distance themselves from mainstream psychology, which some find insufficiently based on biology or natural science as a whole. American psychologist Knight Dunlap (1875–1949) was undoubtedly one of the pioneers of *biological psychology* (or *psychobiology* as he preferred to call it) and defined it in his book “An Outline of Psychobiology” (Dunlap 1914) as the study of the relationships between mental and physiological functions.

Biological psychologists will use experimental techniques from behavioral science as well as concomitant methods and strategies from neuroscience and biology – their experimental subjects can be human volunteers, brain-diseased patients, or laboratory animals (most commonly rats or mice, sometimes nonhuman primates). A common strategy used by biological psychologists is the introduction of a biological manipulation in experimental animals (brain lesions, drug administration, genetic procedures including selective breeding and transgenic or RNA interference techniques, etc.) and the ensuing observation of its effects on behavior. These manipulations are often used to construct an animal model of a neurological or psychiatric disease that can be behaviorally studied and used in preclinical behavioral studies to assess the efficacy of a therapeutic procedure (e.g., preclinical assessment of the efficacy of antidementia drugs or environmental enrichment in prevention or reversal of learning and memory defects in rodent models of dementia). Recent advances in biological imaging and electrophysiological recording techniques have contributed to their use in biological psychology. Noninvasive functional imaging techniques including ► [functional magnetic resonance imaging \(fMRI\)](#), positron emission tomography (PET), or single-photon

emission tomography (SPECT or SPET) are often used to record brain activity in human or animal subjects during the performance of specific behaviors or mental operations (e.g., brain imaging in a human volunteer who is reading a text or solving a mathematical problem). More invasive techniques are sometimes used in experimental animals to record electrical activity in specific brain regions or even in single brain cells, or the release of minute amounts of brain chemicals, during behavioral performance. Stimulation electrodes can be implanted to investigate the effects of local brain stimulation on behavior in freely moving animals.

Many biological psychologists have been involved in specific aspects of the research on behavioral genetics and behavioral pharmacology (psychopharmacology). One of the most exciting recent developments is the gradual emergence of the subdiscipline of molecular psychology that focuses on the molecular neurobiology of behavior. The term was first used by science journalist and Pulitzer laureate Jon Franklin in his 1987 book “Molecules of the Mind” (Franklin 1987). According to Franklin, the origins of the subdiscipline coincide with crucial discoveries in the discipline of psychopharmacology (notably in the lab of Johns Hopkins neuroscientist Solomon Snyder). This view would relate the biological causes of psychology mainly to molecular processes taking place at the contacts (synapses) between nerve cells (neurons). More recently, molecular psychology has been recoined in relation to the discovery of complicated signal transduction pathways inside living cells that form the basis of the molecular processes underlying neural and behavioral plasticity. Specialists feel that progress in this still largely unexplored subdiscipline may eventually contribute to novel treatments for presently incurable brain diseases.

Biological psychologists usually hold an academic degree in psychology and/or are working in psychology departments of a scientific institute. The emphasis of their work is on behavior or behavioral disorders, but apart from measures that originate from the field of psychology, they tend to use also a variety of research techniques

from biology and biochemistry, pharmacology, or biomedical science, depending on the level of explanation they are interested in. Biological psychologists investigate proximate as well as ultimate causes of behavior. Some may even try to integrate these complementary levels to reach a more comprehensive explanation of behavior as ethologist Niko Tinbergen (1907–1988) proposed more than 40 years ago. Proximate explanations may include neurochemical processes (interactions between molecules in the nervous system, cellular metabolism, molecular pharmacology, etc.), processes at the cellular level (interactions between neurons or between neurons and glial cells, transmission of neural impulses, electrophysiological functions of the neuron, etc.), or those at the level of different brain systems (e.g., interactions between different anatomical brain structures or between functionally/neurochemically distinct parts of the central nervous system). More ultimate explanations of behavior would include those that relate to ontogenic development during an organism's life or to the tentative reconstruction of evolutionary history within its ecological context (i.e., the subdiscipline of evolutionary psychology).

Self-identification

Science

Biological psychology definitely self-identifies as an empirical science and applies scientific methodology to the study of the biological basis of mental processes and behavior. It accumulates knowledge and builds theories through discovery- or hypothesis-driven observation and experimentation. All data and methodology are stored, documented, and archived as a precondition for statistical examination of their validity and reliability and should be available to other researchers for reproduction and verification. None of the theories or hypothesis in *biological psychology* should be considered absolute truths or unquestionable knowledge. The field focuses on the relationship between psychological processes and the underlying physiological, genetic, and molecular mechanisms, and it thus aims to

uncover the biological basis of behavior, emotion, motivation, perception of internal and external stimuli, sleep, learning and memory, etc. By comparing these processes across different species, it is related to comparative psychology. Some research in *biological psychology* could be called truly fundamental in that it has no primary practical purpose, but much of it is geared to solving clinical problems or to improve the human lot in some other way. Notably, knowledge acquired by biological psychologists may improve the treatment or prevention of brain disorders (e.g., Parkinson's or ► [Alzheimer's disease](#)).

Religion

Methodology and theories, history, and recent progress, *biological psychology* accept observable, empirical, and measurable evidence as its only source of knowledge and formulates hypotheses and theories that are experimentally validated. However, it does remain a typically human activity and may thus not be as value- or culture-free (or objective for that matter) as it claims to be, but all of its students will most strongly agree that none of its theories are entirely incontestable and that the science of *biological psychology* remains a work in progress.

Characteristics

Defining *biological psychology* rather generally as the empirical study of the biological attributes of behavior renders it very difficult indeed to distinguish this discipline from behavioral neuroscience, neuropsychology, biological psychiatry, comparative neurology or psychology, ethology, etc. The crucial issue, however, is mostly one of identification, and thus, the distinction might be least fuzzy at the level of the methods used and/or the basic training of workers in these obviously highly related disciplines. For example, behavioral neuroscience is probably the most similar discipline, largely identical in scope and practice to *biological psychology*, but this term is commonly used to denote the *multidisciplinary* study of neural processes at the basis of behavior.

Specialists trained in biology, biochemistry, pharmacology, or biomedical science (including psychiatrists and neurologists), who investigate behavior or behavioral disorders, may all, at a certain point in their scientific career, identify as behavioral neuroscientists, but scarcely as biological psychologists. Also, the related discipline of ethology is considered to be a distinct subdiscipline of biology that includes the study of animal behavior in its ecological or evolutionary perspective, but the topics of interest and the methods used, as well as the journals that publish ethological findings, show a high degree of overlap with *biological psychology*. Animal psychologists, on the other hand, might be interested in animal behavior and behavior modification without their link to biology. Finally, neuropsychology is mostly identified as a clinical discipline that includes the use and development of psychodiagnostic instruments in neurological and psychiatric clinical practice and the study of the psychological characteristics of brain-diseased patients.

Sources of Authority

Famously, Galileo Galilei (1564–1642) has been attributed to have said that in science “the authority of a thousand is not worth the humble reasoning of a single individual.” Like other empirical sciences, *biological psychology* does not formally acknowledge the absolute authority of individuals or sources, but it does have its giants with regard to the pioneering aspect or sheer volume of their contributions. The crucial insight that the brain must be the seat of the mind was held already by Greek philosophers like Pythagoras (BC 570–510) and Plato (BC 427–347). The renowned Persian polymath Avicenna (980–1037) linked physical and psychological illnesses together and, notably, reported an association between changes in pulse rate and emotions.

The start of modern *biological psychology* in the late nineteenth century was inspired by the works of Ernst Weber (1795–1878) and Gustav Fechner (1801–1887), who applied methods of physiology to psychology Schultz and Schultz

(1992). Obviously, Charles Darwin’s (1809–1882) theory of evolution had a broad and far-reaching influence on many fields of psychology as well and inspired the study of mental processes in animals and their comparison across species. One of the founders of scientific psychology, William James (1842–1910), actually treated psychology as a biological science and recognized the importance of the brain for consciousness, but the great Russian physiologist and 1904 Nobel Laureate Ivan Petrovich Pavlov (1849–1936) might arguably be considered the first real biological psychologist.

British physiologist, Charles Scott Sherrington (1857–1952), made seminal contributions to many fields of neurophysiology and devoted his later work to mind-body dualism and the nature of mind. Sherrington was convinced that the mind must be material and argued vehemently against Descartes’ view that nonhuman animals are “automata without a mind.” In the early 1920s, Swiss Nobel Laureate Walter Rudolf Hess (1881–1973) pioneered the use of stimulation electrodes to investigate the effects of local brain stimulation on behavior. In experiments with cats and dogs, Hess observed that applying current to electrodes in the diencephalon or hypothalamus resulted in instantaneous behavioral changes. Hess’ technique has been instrumental, for example, to the study of reward centers in the brain, which has contributed to our understanding of addiction, and the development of the technique of electrical self-stimulation of the brain.

Karl Lashley (1890–1958) assessed the effects of brain damage on learning and memory in laboratory animals. Early in his career, he collaborated with behaviorist John B. Watson (1878–1958) on animal behavior and later with Shepherd Franz (1874–1933) on the effects of cerebral lesions on retention and habit formation in rats. His student, Canadian psychologist Donald Olding Hebb (1904–1985), explored how neural functions contribute to psychological processes and outlined knowledge about behavior and mind in his seminal 1949 book “The Organization of Behavior” (Hebb 1949). Hebb might be rightfully called the father of cognitive psychobiology,

whose ideas exert a persistent influence on neuroplasticity research, and contemporary cognitive and computational neuroscience.

Burrhus Frederic Skinner (1904–1990) is one of the most influential figures in psychology. His stringent methods for the experimental analysis of behavior and operant conditioning are still used by biological psychologists around the world. Also, the work of biopsychologist and 1981 Nobel Laureate Roger Sperry (1913–1994) is still of major significance today. Sperry contributed to our understanding of the functions of the cerebral hemispheres and is still cited for his work on split-brain patients. Torsten Wiesel (1924) and David Hubel (1926) studied information processing in the visual system and the mechanisms of cortical neuroplasticity. In addition, the work of these two Nobel Laureates proved critical for the treatment of visual impairment in children (e.g., congenital cataract and strabismus).

Finally, two psychiatrists-turned-neuroscientists largely determined the face of contemporary *biological psychology* and its modern focus on neuromolecular mechanisms. The first is Eric Richard Kandel (1929), who received the 2000 Nobel Prize in Physiology or Medicine for his research on the cellular basis of memory storage. Realizing that the neuronal mechanisms of learning and memory do not reside in the properties of the neurons themselves but in those of the connections between neurons, he worked on a simple model animal, the giant marine snail *Aplysia* that has a nervous system with a small number of large, easily identifiable cells. During the most recent part of his scientific career, Kandel turned to the study of the mechanism of learning and plasticity in the mammalian brain. The second researcher of interest is Solomon H. Snyder (1938), who is cited for his work on the molecular basis of psychiatric disorders and several major discoveries on the neurochemistry of behavior.

Ethical Principles

As an empirical science, *biological psychology* subscribes to the principles of rigorous and reliable observation and experimentation and to

international legislation and rules that govern scientific publication and authorship. It acknowledges human equality and freedom and the intrinsic value of human and animal life. In as much as *biological psychology* is a laboratory science, it subscribes to the principles of *Good Laboratory Practice*, and the ethical rules for the experimental use of human and animal subjects. In Europe, strict legislation has been included at the level of the *European Union* that applies to the use of animals and humans in research. It is generally accepted, and part of contemporary legislation that the use of animals in research should be justified and evaluated by ethical review procedures. The use of nonhuman primates deserves particular consideration because of their high level of social and cognitive performance and their neurobiological similarity to our own species.

Key Values

Central to this field is the accumulation of empirical knowledge and its application to the benefit of the human condition. Specific values of *biological psychology* include (1) continuous search for biological mechanisms underlying mind and behavior in a purely scientific, reproducible way; (2) cross-species comparison of these mechanism to identify evolutionary principles; (3) application of research findings for the diagnosis, prevention, and treatment of brain disorders; and (4) replacement of invasive methods of investigation by noninvasive techniques (e.g., noninvasive brain imaging).

Conceptualization

Nature/World

The physical world including the dynamics and properties of organic matter, organisms, etc. The human species is part of nature.

Human Being

A primate that evolved as a result of biological evolution and natural selection and a member of the biological species *Homo sapiens sapiens*. Although biological psychologists tend to regard

humans as part of a biological continuum that stretches from unicellular organisms through vertebrate species, they do acknowledge the special family-like responsibility that humans have with regard to other members of their kind. This special responsibility, which is laid down in legislation and ethical principles, obviously includes young children and mentally impaired individuals as well, even though from a purely biopsychological point of view, such human beings might have more limited mental capacities than some of our highly developed animal relatives. Notably, this responsibility is the principal justification for the use of animals in *biological psychology* and other fields of science.

Life and Death

Although not a direct object of their scientific work, biological psychologists would consider that life on earth has originated from natural causes. Most of them would hypothesize that the processes of biological evolution form the emergent origin of biodiversity and life on earth, and that, consequently, the human species is a result of natural selection. Life is defined in its biological sense and its relation to physical activity, metabolism, and reproduction. Since it is definitely one of the central tenets of this discipline that biological processes determine the human psyche – the cessation of these biological processes hence coincides with death. For all practical reasons, human death is defined as a state without brain activity.

Reality

The living and nonliving matter that can be perceived by organisms at a variable qualitative and quantitative degree depending on the complexity and performance of their sensory cells or organs. Individual representations of reality after sensory processing can be stored by nonhuman organisms in specialized cells or brain and by humans, additionally, in written form or on electronic media. Humans have increased their ability to perceive reality by taking advantage of physical devices that can measure modalities/traits of reality that otherwise would not be accessible.

Knowledge

Collectivity of skills, expertise, information, and data about the external and internal world, passed on across generations traditionally by means of writing, speaking, imitation of the behavior of relatives or conspecifics (also important in some animal species) and nowadays electronically. Acquisition of knowledge involves complex cognitive processes like perception, association, learning, communication, and reasoning. Biological psychologists aim to unravel the cognitive and neural mechanisms that underlie these processes. Knowledge is classified into categories (animals), disciplines, and theories and kept/stored either collectively in the brains of a given population or in books and on electronic media.

Truth

There are obviously no absolute truths in *biological psychology*, but there are facts, propositions, theories, and hypotheses. Notorious evolutionist Thomas H. Huxley (1825–1895) argued that truths often begin as heresies and end as superstitions, illustrating the relativity of truth or verity. Truth is practically defined by scientists as the propositional status of being in accordance with existing knowledge, in concordance with reality, or the result of experimental verification of hypotheses. The truth or verity of an assumption, hypothesis, or theory can be tested and falsified. It can be demonstrated by putting it to practice, or as stated by William James (1842–1910), “the ‘true’ is only the expedient in our way of thinking, just as the ‘right’ is only the expedient in our way of behaving” (James 1911).

Perception

The process whereby sensory stimulation is translated into biologically/physiologically meaningful information that is further processed, reconciled with existing experience (knowledge), leading eventually to the instant activation of certain behavioral programs like defense, flight, etc. Historically, Gestalt psychologists like Max Wertheimer (1880–1943), Kurt Koffka (1886–1941), and Wolfgang Köhler (1887–1967) tried to identify brain mechanism that account for

perception. Gestalt psychology supposed that perceptual organization reflects innate properties of the brain itself. Thus, perception and brain functions were considered to be formally identical. At about the same time, behaviorism, founded by John B. Watson (1878–1958), described behavior using objective terms such as stimulus and response. Behaviorism denied that perception is amenable to direct investigation, but rather its properties can be inferred from objectively measured behavior.

Time

Time is a fundamental dimension of the surrounding world and all mental and physiological processes. Organisms have adapted to time-dependent changes in their environment (e.g., daily, seasonal, lunar, and tidal geophysical cycles) by developing internal clock mechanisms allowing rhythmicity in internal body functions and behavior that are maintained even during constant environmental conditions (e.g., polar night). In mammals including humans, the most important cycle is the circadian cycle that is driven by hierarchically organized internal clock mechanisms that are synchronized by the day-night rhythm of the sun. At the core of the mammalian circadian system is the oscillatory expression of several “clock” genes such as *Period* (*Per1–3*) and *Cryptochrome* (*Cry1–2*) within the hypothalamic suprachiasmatic nuclei (SCN) that is regulated by autoregulatory transcriptional/posttranslational feedback loops. This clock/pacemaker in the SCN acts as a master clock synchronizing remote clock mechanisms in other central neural circuits, peripheral organs, and tissues and synchronizes these rhythms to each other and to solar time (Challet 2007). Many studies have highlighted the dominant role of the circadian clock system in the organization of 24-h patterns of behavior and physiology. It not only permits humans to estimate time in the absence of clocks and other sensory cues but also allows anticipatory physiological changes even before the periodic change in the environment occurs (e.g., in transmitter and hormone levels). Biological rhythms also depend

on temperature (e.g., experiments in human subjects have shown that time between events is underestimated when body temperature increases). Biological time, as determined by the internal clock system and developmental genetic programs, can be measured and is thus distinguished from “psychological time” (i.e., subjective/private time that is vitally important in many cognitive processes).

Whereas the seventeenth-century English philosopher John Locke (1632–1704) thought time to be only perceived as a relation between successive sensations, William James (1842–1910) used the term “specious present” for the span of time covered by a single act of awareness. He argued that at a given moment of time, a person is aware of events a short time before that time. Humans (and probably higher primates as well) have an awareness of the passage of time even during sleep. However, if knocked unconscious or during anesthesia, this awareness is lost and psychological time appears to stop. Amnesic patients with functional deficits in brain regions that are important for memory storage and recall lose the ability to estimate the passage of time accurately at the scale of hours, months etc., although their biological clock is often intact. This suggests that the processing of time and certain types of memory must share some common mechanisms and pathways.

The psychological sensation of equal periods of time can be quite different, depending on attention and emotions (cf. psychological time when we are waiting anxiously for the start of an exam). The mechanism that is responsible has been termed “interval timer.” Its main constituents are neural oscillators in the cerebral cortex that are all firing at different rates; spiny neurons in the striatum that keep track of elapsed time by using these distinct, cortical firing patterns; and neurons in the substantia nigra that create on/off signals by releasing the neurotransmitter dopamine into the striatum and thalamic neurons, which feedback to the cortex upon completion of time recording. Whereas the precision of the “interval timer” is rather low, its flexibility is remarkable, and it can be stopped at any time by

conscious control or even ignored (Meck et al. 2008). Notably, drugs like cannabis, mescaline, and methamphetamine and brain disorders like schizophrenia, Parkinson's and Alzheimer's disease have been reported to alter the sense of time.

Consciousness

Consciousness involves a set of loosely related thoughts, perceptions, and emotions. Biological psychologists tend to define it as the ability to perceive your experiences and to be self-aware. It is a mental state based on the function of specific brain regions that include prefrontal cortex and thalamus. Consciousness may be altered in brain disease or damage and influenced by psychoactive drugs. Some primatologists argue that forms of consciousness definitely also exists in apes (notably chimpanzees and bonobos) – and other highly developed animals may experience some form of conscious awareness (e.g., cetaceans), which is by and large difficult to determine or define.

Rationality/Reason

This is the ability to act, behave, think, and infer (1) within their evolutionary boundaries; (2) to the benefit of the group (of congeners) the particular organism belongs to; (3) in accordance with acquired experience and knowledge; and (4) consistent with conclusions and imaginations that can be (logically) derived from the former. Rationality is based on the rejection of conventional religion and pseudoscience. It may be impaired in brain disorders or influenced by psychoactive drugs.

Mystery

Mystery is of no particular professional concern to biological psychologists, but there are unsolved questions and staggering complexities in relation to brain and behavior. All things material (including the human brain and its capacities and attributes) can be the object of scientific investigation. Our knowledge about many natural phenomena is still very incomplete, but it merely requires the right equipment and methods, as well as scientific stamina, to tackle these topics in due

course. All that is not part of the natural or physical world is beyond the scope of the empirical science of *biological psychology*.

Description

Biology (derived from the Greek word “bios” meaning “life” and “-logia” meaning “study of”) is a science of living systems (also called organisms) and their processes, including their origin, evolution, development, structure, function, distribution, and classification (or taxonomy). Although the term originated in Germany in the late eighteenth century, the systematic

study of life traces back at least to Hippocrates (ca. 460 BC–370 BC) and Aristotle (384 BC–322 BC). Just as physics can be divided into macroscopic physics (or classical physics) and microscopic (i.e., quantum) physics based on the discovery of the quantum of action by M. Planck (1858–1947) in 1900 and the subsequent emergence of quantum physics in the 1920s, so biology may be divided into macroscopic biology (i.e., the traditional or classical biology dating back to 500 BC or earlier) and microscopic biology (or molecular biology) beginning with the discovery in 1953 of the double helix structure of DNA (deoxyribonucleic acid) by Watson (1928–) and Crick (1916–2004). Two of the most important advances in microscopic biology are (1) the cell theory formulated by T. Schwann (1810–1882), M. J. Schleiden (1804–1881), and R. Virchow (1821–1902) between 1839 and 1855; and (2) the theory of evolution proposed by Darwin (1809–1882) in 1859.

The generally accepted cell theory includes the following elements: (1) All organisms are made up of one or more cells; (2) all living cells, except those originating from abiotic system at the origin of life 3–4 billion years ago, arise from preexisting cells; (3) the cell is the basic unit of structure and function of all organisms; (4) the free energy, without which no cells can survive, is supplied by the chemical reactions (i.e., metabolism including photosynthesis) occurring within cells; and (5) the genetic information which is necessary to regulate metabolism, and hence the energy supply to cells is encoded in the nucleotide sequences of DNA that is transmitted from one cell generation to the next.

According to E. Mayr (1904–2004) (Mayr 1991), Darwin’s theory of evolution is not just a single theory but contains at least four sub-theories: (1) Organisms are not permanent but change in time; (2) species multiply by branching into daughter species or by forming founder populations that evolve into new species; (3) evolutionary changes occur gradually and not by the sudden production of new individuals belonging to a new species; and (4) evolution occurs through (a) variation of heritable traits and

(b) selective survival of individuals adapted to their environment.

Of these sub-theories, (1) and (2) have been amply confirmed by empirical data. Sub-theory (3) seems inconsistent with both paleontological data (Eldredge and Gould 1972) and the generalized Franck-Condon principle, a principle imported from physics and found to apply to a wide range of living processes (Ji 2012, pp. 21–24). Concerning the component (a) of sub-theory (4), the mechanisms underlying the “variation of heritable traits” can include not only *random mutations* as widely accepted in modern synthesis (also called neo-Darwinism) but also *nonrandom mutations* such as recombination (i.e., breaking and rejoining of DNA strands to form new molecules of DNA with a novel set of genetic information) and what was recently referred to as “active complexification” (Ji 2012, pp. 127–129, 496–498) as exemplified by “facilitated variations” of Kirschner and Gerhart (Kirschner and Gerhart 2005).

There are many noteworthy developments that have occurred since 1953 when the era of “microscopic biology” (also called “molecular biology”) began. Some of these developments are described below:

DNA Sequencing Revolution. The era of microscopic biology may be said to be ushered in with the determinations of the 3-dimensional structures of DNA and myoglobin by Watson (1928–) and Crick (1916–2004) and by J. Kendrew (1917–1997) and M. Perutz (1914–2002), respectively, in the mid-1960s, using the X-ray crystallographic method invented by W. L. Bragg (1862–1942) and W. H. Bragg (1890–1971) about a half century earlier. The linear sequence structures of DNA molecules began to be determined in 1977 by Maxim and Gilbert and Sanger et al. (Tucker et al. 2009) leading to the development of the massively parallel and high-throughput, *next-generation DNA sequencing technologies* in the beginning of the twenty-first century (Tucker et al. 2009). The cost of sequencing a genome (i.e., the totality of an organism’s genetic information encoded either in DNA or RNA, the genome including the

protein-coding and noncoding sequences of DNA/RNA) has gone down by three orders of magnitude since 1977 and is expected to go down by a similar factor in the near future to about \$1,000 per genome (Tucker et al. 2009). The high-throughput, massively parallel DNA sequencing technologies are expected to generate massive amount of sequence data, the correct interpretation of which will require experts trained in *bioinformatics*, the new field applying computer science and information technology to biomedical sciences. Bioinformaticians must be knowledgeable in algorithms, databases and information systems, web technologies, software engineering, data mining, image processing, structural biology, modeling and simulation of dynamic processes, signal processing, discrete mathematics, control and system theory, circuit theory, network sciences, and statistics, in addition to the basic laws and principles of theoretical cell biology. The combination of the high-throughput DNA sequence data and their correct interpretations provided by bioinformaticians are expected to open up a new era in biomedical sciences in the coming decades including personalized medicine and rational drug design and discovery researches around the globe.

What Is a Gene? The history of the concept of the gene is at least one and a half centuries old, but its definition is still in flux. The concept of a gene as a heritable trait was established through the experiments with pea plants performed by the Austrian monk G. Mendel in the mid-nineteenth century. The term “gene” itself was coined by W. Johannsen in 1909 in analogy to the term “pangene” used by Darwin in formulating his ill-fated pangenesis hypothesis. The modern idea of a gene as a sequence of nucleotides in DNA was established by three main discoveries: (1) Avery, MacLeod, and McCarthy found that DNA is the carrier of genetic information; (2) Watson and Crick discovered that DNA is a double helix formed from two complementary strands of deoxyribonucleic acid; and (3) the discovery by Crick, Brenner, Watts-Tobin, Nirenberg, Matthaei, and Khorana that triplets of nucleotides code for amino acids. These and other historical facts about the evolution of the

gene concept have been reviewed in (Gerstein et al. 2007). Prior to 2007, when the results of an international research effort known as the ENCODE (Encyclopedia of DNA Elements) Project was announced, the definition of gene was simple: *DNA segments encoding RNAs leading to protein synthesis*. But the ENCODE project has revealed numerous findings that cannot be readily accommodated by such a simple conception of a gene, and a new definition of a gene is called for. One way to overcome the problems brought up by the ENCODE project was suggested to be to postulate that there are two classes of genes – the S-genes and P-genes, where S and P stand for “structure” and “processes.” The former is identified with the pre-ENCODE conception of genes, also called the Watson-Crick genes, and the latter is a new class of genes called the Prigoginian genes (Ji 2012, p. 232). S-genes are analogous to *sheet music* (or written language), and P-genes are analogous to *audio music* (or spoken language). Just as the sheet music is converted into audio music by a pianist, so the Watson-Crick genes are postulated to be transduced into Prigoginian genes by enzyme systems acting as *molecular machines* driven by *conformons*, the sequence-specific conformational strains (Ji 2012, p. 231–243). It is possible that the failure of the pre-ENCODE conception of a gene can be traced ultimately to the following fact: *Biologists have been measuring the functions of genes (which belongs to the class P of processes) and attempted to reduce the results to nucleotide sequences of DNA (which belongs to the class S of static structures), without specifying the requisite molecular mechanisms (which belongs to the class M of mechanisms)*. In other words, they equated P and S which belong to two different classes (and hence could not be equated) rather than relating P and S through M, the critical link.

Blackbody Radiation-Like Equation (BRE). The last decade of the twentieth century witnessed two revolutionary experimental techniques to emerge in molecular and cell biology – the *single-molecule manipulating techniques* and the *DNA microarray technique*. In 1998, using the optical tweezer technique, Xie and his group for the first time measured the rate constants of

a single molecule of cholesterol oxidase (Ji 2012, Sect. 11.3). One of the most unexpected findings is that the rate constant of the catalytic activity of one enzyme molecule is not fixed as previously thought but varies from one catalytic cycle to the next. They measured about 1,500 rate constants (also called waiting times) from a single molecule of the enzyme over a period of 5 to 20 min. When these rate constants are grouped into bins (i.e., rate constant classes) covering the range from 10 to 250 ms, the frequency of each bin is counted, and these are plotted on a 2-dimensional graph, a histogram was obtained. The shape of this histogram was non-Gaussian and found to fit a mathematical equation called the “blackbody radiation-like equation” (BRE) that is similar in form to the blackbody radiation equation discovered by M. Planck in 1900 which introduced the concept of “quantization” of energy into physics. The fitting of the single-molecule enzymic data into BRE thus can be interpreted as indicating that the Gibbs free energy level of an enzyme molecule is quantized (Ji 2012, Sect. 11.3.3). One consequence of this interpretation is that the rate constant of an enzyme molecule is completely determined by the ground-state Gibbs free energy levels of the enzyme. What is even more unexpected is the finding that the BRE also fit the experimental data obtained from two other biological processes – the protein folding Gibbs free energy data and the whole-cell RNA level data measured from budding yeast (Ji 2012, p. 436).

DNA Microarray Revolution and Intellectual Crisis in Biology. In the mid-1990s, biologists at Stanford University developed a revolutionary technique known as DNA microarrays. A DNA microarray consists of a microscopic slide, typically 2 cm by 2 cm in dimension, divided into 10,000 squares, on each of which are chemically attached hundreds of copies of a whole gene or its characteristic fragments that encode an RNA molecule (http://en.wikipedia.org/wiki/DNA_microarray). Thus, using one microarray, it is possible to measure simultaneously the levels of 10,000 RNA molecules in a biological sample. It is becoming increasingly clear that the massive amount of genome-wide expression

(i.e., transcription of genes to RNA molecules) data generated by the DNA array technique can no longer be rationally accounted for solely on the basis of the principles and knowledge gained from *test-tube* molecular biology alone, but new *whole-cell* approaches and perspectives need to be developed in order to enable biomedical scientists to correctly interpret DNA microarray data and extract biologically meaningful information from them. It is truly astounding to find that most of the papers published since the invention of the microarray method in the mid-1990s have erred in interpreting microarray data, resulting in false-positive and false-negative conclusions (Ji et al. 2009) which led some biologists to conclude that there exists “an intellectual crisis in the field of DNA microarray data analysis” (see Appendices C, D, E and F in (Ji 2012)). Despite these difficulties in interpreting microarray data in molecular terms (i.e., genes and gene expression), microarray techniques, used as a phenomenological tool, however, are making valuable contributions to both basic biomedical sciences and medicine. For example, two important findings have merged in recent years from the DNA microarray data measured from budding yeast undergoing nutritional stress (i.e., changing the energy source from glucose to galactose) – (1) the quasi-determinism of genotype-phenotype coupling, an observation that indirectly supports the cell language theory (Ji 2012, pp. 159, 420–433); and (2) and the quantization of the Gibbs free energy levels in the living cell, an evidence for the existence of the cell force (Ji 2012, 444–461) (see below).

Quasi-deterministic Genotype-Phenotype Coupling. A genotype refers to a unique nucleotide sequence pattern in a DNA molecule, and a phenotype is any effect (e.g., shape of a cell, color of hair) or products (e.g., DNA, RNA, proteins) produced by a gene either directly (e.g., through transcription) or indirectly (e.g., by coding for a transcription factor that affects the transcription of other genes). In principle, there are four possible genotype-phenotype relations – (1) one-to-one (i.e., one gene codes for one phenotype), (2) one-to-many (i.e., one gene codes for many phenotypes), (3) many-to-one (i.e., many

different genes code for one phenotype), and (4) many-to-many (e.g., an identical set of genes code for many different phenotypes). These relations can be divided into two groups – deterministic and quasi-deterministic. The one-to-one relation is deterministic in that a gene, for example, completely specifies not only the nucleotide sequence but also the copy number of its RNA, and the other relations are quasi-deterministic in the sense that a gene can specify completely only the nucleotide sequence but not the copy number of its RNA molecule (Ji 2012, Sect. 12.9).

The RNA trajectories measured by Garcia-Martinez et al. (2004) provide indirect experimental evidence for the quasi-deterministic relation between structural genes and their phenotypes, that is, their RNA levels in the cell. Each of the over 6,000 RNA traces (or trajectories) measured by Garcia-Martinez et al. (2004) using DNA microarrays in budding yeast undergoing glucose-galactose shift carries two kinds of information – (1) the name of the gene encoding the RNA molecule whose concentration is being measured, and (2) the time-dependent change in the intracellular concentration (or copy number) of the RNA. The former can be represented in the N-dimensional sequence (or *genotype*) space, where a point represents an N nucleotide-long RNA molecule, and the latter in the 6-dimensional concentration (*phenotype*) space, wherein a point denotes the kinetic trajectory of an RNA molecule measured at six time points. Thus, for any pair of RNA molecules in budding yeast, it is possible to calculate (1) the *genotypic similarity* as the degree of the overlap between the pair of nucleotide sequences (using the ClustalW2 program on line) and (2) the *phenotypic distance* as the Euclidean distance between the corresponding two points in the 6-dimensional concentration space. When the *phenotypic distances* (PD) of a set of all possible RNA pairs (y values) were plotted against the associated *genotypic similarities* (GS) (x values), a scatter lot was obtained wherein all the points were found to lie under a *diagonal line* with a negative slope. This triangular distribution indicates that structural genes have an effect on the intracellular levels of their

own transcripts, because, otherwise, *the distribution of the points on the GS vs. PD plot should be random. On the other hand, if structural genes had a complete control over their intracellular transcript levels, all the points should lie on or along the diagonal line*, but only a small fraction of the points actually was found to lie close to it. More than 95 % of the points were found to be contained in the region below the diagonal line. So the relation between genotype and phenotype as revealed in the GS vs. PD plot embodies some regularities, but these regularities are unpredictable, leading to the conclusion that the genotype-phenotype relation is *stochastic* or *quasi-deterministic*, reminiscent of the principle of rule-governed creativity or arbitrariness of signs in linguistics (Ji 2012, Sects. 12.9 and 12.10).

Cell Language. Language is not the monopoly of humans. Living cells are found to use language on the molecular scale. Cell language is defined as “a self-organizing system of molecules, some of which encode, act as signs for, or trigger, gene-directed cell processes” (Ji 2012, p. 164). What is surprising is the finding that 10 out of the 13 design features of human languages characterized by linguists have molecular counterparts in cell language, leading to the notion of the *isomorphism between human and cell languages*. Just as human languages are based on *double articulation*, that is, the formation of sentences from words (called *first articulation*) and the formation of words from letters (*second articulation*), so cell language embodies a double articulation in that there are two and only two kinds of mechanisms for changing molecular structures – *conformational* (also called noncovalent) changes corresponding to the first articulation and *configurational* (also called covalent) changes corresponding to the second articulation. In both human and cell languages, double articulations appear necessary for efficient communication, that is, the storage, transfer, and transformation of information.

The Cell Force. The microarray data measured by Garcia-Martinez et al. (2004) can be mapped onto a cluster of points in a 6-dimensional *RNA concentration space* wherein each point represents an RNA trajectory consisting of a set of

six RNA levels. The similarity between the shapes of any pair of RNA trajectories can be calculated as the Euclidean distance between two points in the concentration space. It was found that most (70–90 %) of the Euclidean distances between all possible RNA pairs belonging to a given metabolic pathway obeyed the black-body radiation-like equation (BRE), $y = (a/(Ax + B)^5) / (e^{b/(Ax + B)} - 1)$, where x is distances between RNA trajectories, y is the frequency of observing a given distance class, and a , b , A , and B are constants. The fitting of the RNA data into BRE has been interpreted as the evidence (1) that *thermal fluctuations* (or Brownian motions) of transcriptosomes (catalyzing the transcription of DNA to RNA) and degradosomes (catalyzing the degradation of RNA) play an important role in the control of their activities and (2) that the Gibbs free energy levels of transcriptosomes and degradosomes are *quantized*. Just as the quantization of the energy of electrons in an atom led to the notion of atomic orbitals in physics almost a century ago, it appears that the quantization of enzyme complexes (e.g., transcriptosomes and degradosomes) in living cells may indicate the existence of “cell orbitals” which determine their catalytic activities. Again, just as atomic orbitals can be visualized in terms of geometric objects (e.g., spheres, lobes) which are invariably symmetric, “cell orbitals” can be visualized as a 5-dimensional Gibbs free energy surface whose topology (i.e., shape and curvature) varies in space and time. Such a dynamic geometric object was named the “time-dependent Gibbs free energy landscape” (TGFEL) (Ji 2012, p. 460), which can be viewed as the geometric representation of the *cell force*, the causal agent postulated to be responsible for the metabolic organization of the living cell (Ji 2012, pp. 444–461). It may turn out *that TGFEL is to the cell force that the Calabi-Yau manifolds are to the strong force* (Yau and Nadis 2010). If analytical geometers can prove the validity of this conjecture in the future, we would be able to state with confidence that there exists a new force in nature (in addition to the strong, weak, electromagnetic, and gravitational forces) that is responsible for life.

Conformons and Molecular Machines. According to Bruce Alberts of the University of California, San Francisco, the cell, the basic unit of life, is “a collection of protein machines,” *protein machines* being synonymous with *molecular machines*. We now have experimental evidence (Ji 2012, pp. 231–246, 444–448) (1) that all molecular machines are driven by packets of the mechanical (i.e., conformational) energy (called *conformons*) stored in sequence-specific sites in molecular machines themselves and (2) that the motions of millions of molecular machines in a given cell are not random but organized in space and time in order to accomplish gene-directed cell functions through the action of the *cell force*. The cell force is defined in analogy to the strong force in physics: *Just as the strong force holds nucleons (i.e., protons and neutrons making up atomic nuclei) together against electrostatic repulsion, so the cell force holds together biopolymers and small molecules together in the living cell in functional states despite the randomizing effects of thermal motions* (Ji 2012, pp. 444–461, 679–689). It appears logical to conjecture that the cell force can be represented geometrically as the curvature of the time-dependent Gibbs free energy landscape (TGFEL) (Ji 2012, Fig. 12.32), just as the gravitational force can be represented as the curvature of space-time and the other fundamental (i.e., strong, weak and electromagnetic) forces as the curvatures of corresponding Calabi-Yau surfaces or manifolds (Yau and Nadis 2010).

Molecular Theory of the Living Cell. Although the *cell theory* maintaining that all organisms consist of one or more cells was formulated by the early decades of the nineteenth century, there was no theoretical model of the living cell published until the Bhopalator was proposed in 1985 (Ji 2012, pp. 269–279). The Bhopalator model of the cell contains four theoretical components – conformons proposed in 1972–1974, IDSs and the cell force both proposed in 1991, and the cell language theory formulated in 1997. But it took another decade and a half to recognize that these theoretical components are not independent of one another but inseparably

interlinked, representing different aspects of the same object, that is, the living cell. This idea is represented geometrically as a body-centered tetrahedron (Ji 2012, p. 278) (Fig. 1):

Cell Biological Theories of Evolution. Darwin’s theory of biological evolution was published in 1859 and, according to E. Mayr (1904–2005), consists of the following four sub-theories:

1. Organisms are not permanent but change in time.
2. Species multiply by branching into daughter species or by forming founder populations that evolve into new species.
3. Evolutionary changes occur gradually and not by sudden production of new individuals belonging to a new species.
4. Evolution occurs through (a) variation of heritable traits and (b) selective survival of individuals adapted to their environment.

Items (1) and (2) have been confirmed by empirical data. Some evolutionary biologists may dispute the validity of item (3) based on the theory of punctuated equilibrium. Applying the generalized Franck-Condon principle to evolution, it can be predicted that phylogenesis (i.e., the evolutionary development of groups of organisms) will be rate limited by the speed of geological changes (Ji 2012, p.23), which would be consistent with the idea of punctuated equilibria. Item (4) may also be viewed as confirmed by empirical data, although the microscopic mechanisms underlying the variation of heritable traits are still poorly understood.

As is well known, Darwin’s theory of evolution is a controversial topic and has been attracting the interest of both scientists and lay public, ranking among the most widely discussed subjects on the Internet. For example, *evolution theory* has been visited by more people than *Einstein’s relativity theory* as of August, 2009, and is comparable to the topic of Obama’s cabinet in terms of the number of visitors. Darwin’s theory of evolution is a *macroscopic* theory formulated one and a half centuries ago in order to account for the then-available *macroscopic* data about organisms. Consequently, the key elements

Biology, Fig. 1 The molecular theory of the living cell geometrically represented as a body-centered tetrahedron containing four external vertices connected through six external edges. The internal node is connected to the four vertices via three internal edges

of Darwin's theory (see above) may be remote from, and shed little light on, the microscopic (i.e., molecular and cellular) data on organisms that have been accumulating in biology since the publication of Darwin's theory of evolution. Just as Newtonian mechanics formulated in the late seventeenth century failed to account for the microscopic observations made in the late nineteenth century (e.g., blackbody radiation, atomic line spectra, the photoelectric effect), so it would not be surprising to find that Darwin's theory of evolution published one and a half centuries ago sheds little light on certain molecular aspects of living systems that were measured only in the twentieth century (e.g., the role of DNA in inheritance and morphogenesis, the genetic codes, signal transduction cascades, the cell cycle, cell differentiation, genetic drift). This is why it is essential to formulate a *microscopic theory of biological evolution* that can not only account for molecular data on living systems but also subsume the Darwinian theory of evolution, just as quantum mechanics subsumes Newtonian mechanics. Such theories (referred here as *cell biological theories* of evolution) have begun to appear in recent

decades (reviewed in (Ji 2012, pp. 494–506)), which should shed new light on the contemporary debates on biological evolution.

Self-identification

Science

Natural sciences are characterized by systematic studies of nature using measurements/observations, analysis based on existing theories, hypothesis building, and hypothesis testing against experimental observations followed by modification of existing theories if necessary. Biology contains all these aspects, and hence, there is no doubt that biology is a scientific field.

Religion

Depending on how one defines a religion, biology may be included as a member of such a religion. To some biologists, the distinction between *theory* and *theology* can be blurry. Thus, it is not uncommon to witness prominent experimental biologists referring to what theoretical biologists do as "theology." Just as we can regard topology

and geometry as the global and local definitions (or as type and token), respectively, so it may be useful to distinguish between global and local definitions of religion.

Characteristics

Biology is the science of life and living systems. In this sense, it differs from physics and chemistry, both of which study primarily nonliving systems.

Relevance to Science and Religion

Biology is relevant to the science-religion debate/discourse because biology provides a scientific perspective on life, whereas religion provides a higher and more global perspective on life which is beyond the domain of scientific inquiry.

Sources of Authority

The source of the authority of biology resides in the fact that all the regularities and laws of organisms and their components were established through the rigorous method of observations, critical analysis, and hypothesis testing by a community of investigators.

Ethical Principles

Probably, the foremost ethical principle in biology, as in other branches of natural sciences, is honesty, which naturally leads to the objectivity of observations and measured data so that they can be reproduced by any biologists anywhere and at any time.

Key Values

The principles and accumulated knowledge of biology are essential in understanding the phenomenon of life at the deepest level, leading to

practical applications in basic sciences, physiology, psychology, medicine, and the philosophy of mind.

Conceptualization

Nature/World

Biologists regard nature as the material world that is accessible to their observations and measurements. They accept whatever model of nature that is established in physics based on microphysical and astrophysical observations in the form of the Standard Model and theories of quantum mechanics and relativity.

Human Being

Human beings are systems of 10^{12} – 10^{13} cells that are organized in space and time, driven by genetic information and free energy supplying chemical reactions. Biologists believe that anatomically modern humans evolved from their earlier ancestors in Africa between 400,000 and 250,000 years ago. The earlier ancestors of *Homo sapiens* ultimately trace their origin to the first living cells that originated on this planet some 3–4 billion years ago through spontaneous generation of self-reproducing chemical reactions-diffusion systems likely driven by thermal gradient on the earth surface or deep in the ocean floor.

Life (and Origins of)/Death

Most biologists believe that life originated on this planet 3–4 billion years ago in the form of unicellular organisms through the interactions among certain rare chemical and physical processes obeying the laws of physics and chemistry and under the constraints of the then-extant environmental conditions.

Reality

Biologists view reality as something that exists in nature prior to measurements and yields records upon being subjected to measurements, accurately reflecting what it (i.e., reality) actually is. Many biologists believe that what cannot be measured does not exist and hence that theoretical biology is of secondary importance as compared to

experimental biology. This way of thinking pervading the contemporary biological community is probably the result of the almost exclusive funding of experimental biological researches over theoretical biological ones. This situation may be slowly changing because of the massive accumulation on the Internet of the biological data measured on living systems and the realization that these data cannot be understood without the help of computers supported by sophisticated statistical analyses and deep biological theories. It is interesting to note that, in physics, there are more theories than can be evaluated by existing data, whereas, in biology, there are more data than can be understood by existing theories. This calls for more experiments to be done than theories in physics and more theories to be developed than experiments in biology. Dozens of international organizations invested billions of dollars to create the LHC (Large Hadron Collider) in Switzerland to produce data to test the validity of many theories proposed by hundreds of theoretical physicists (including Professor P. Higgs) that are published. In contrast, the US government alone has invested billions of dollars to support biological research over the past half a century or more, but there is practically no general biological theory available that can provide the theoretical framework to extract biologically meaningful information from the vast data.

Knowledge

A system of organized information that can be applied to solving practical problems.

Truth

A statement or proposition that has been formulated based on logic and found to agree with experiments or our daily experience.

Perception

The sum total of the stimuli that enters our consciousness leaving behind some registered traces in our nervous system.

Time

A physical parameter that increases unidirectionally just as the entropy of an isolated system does that undergo changes of whatever kinds.

Consciousness

The property of our nervous system that is aware of its own activity, that is, self-awareness.

Rationality/Reason

The ability of our mind to carry out thought processes in accordance with a set of logical rules as well as natural laws.

Mystery

Biology is replete with mysteries. For example, despite the research efforts by hundreds, if not, thousands of biologists around the world during the past half a century or more and the availability of the 3-dimensional X-ray crystallographic and associated amino-acid sequence data of hundreds of proteins, we still do not understand how the amino-acid sequence of even a single protein determines the 3-dimensional structure of the protein. That is, we still cannot predict, based on the laws of physics and chemistry alone, the 3-dimensional structure of a protein from its amino-acid sequence. This may indicate that there exists one or more fundamental laws hidden in protein folds that either have not yet been discovered in physics or chemistry or are beyond these scientific disciplines. One possible solution to this dilemma was suggested to be to postulate that protein folding is determined by two mutually exclusive kinds of factors referred to as the *synchronic* (e.g., physical and chemical) and *diachronic* informations (e.g., linguistic principles) and that the laws of physics and chemistry, representing synchronic information, are necessary but not sufficient to account for protein folding and the evolutionary history, representing the diachronic information, needs to be relied on in addition (Ji 2012, pp. 159–173). Of course, one of the most important mysteries of biology that is relevant to the science-religion discourse is the problem of the origin of life (OL). It may be that OL has two complementary aspects – the *scientific* aspect that is amenable to scientific explanations and the *mystic* aspect that accounts for the gap left behind by science. This idea may be diagrammatically represented as shown in Fig. 2.

Biology, Fig. 2 The scientific and mystic aspects of the origin of life (OL)

Relevant Themes

The relevance of the contemporary biology to the science-religion dialogue was recently summarized in (Ji 2012, p. vii):

The cell is arguably one of the most complex material systems in nature, in no small part because it is the building block of all living systems, including us. *We are cells, and cells are us.* To know how cells work, therefore, will contribute to understanding not only how our bodies work, which will advance medicine, but also how our mind works, which may help answer some of age-old philosophical and religion-related questions from a new perspective. It is hoped that the molecular theory of the living cell presented in this book will contribute to the emergence of ‘the new science of human nature’ that can lead ‘to a realistic, biologically informed humanism.’ (S. Pinker 2003)

In a more practical vein, the emerging molecular theories of living systems may have significant contributions to make in resolving some of the elusive problems raised in contemporary evolution-religion debates.

There are two kinds of empirical data that are involved in debates on evolution – macroscopic (or phenomenological) data such as those Darwin collected during his 5-year trip (1831–1836) around the world on the HMS Beagle and microscopic (or molecular, cellular) data such as those on the role of DNA in genetic inheritance that became available only during the past century. Since fact-based debates on evolution must utilize either one or both of these two kinds of empirical data, we can logically divide all debates on evolution into four main types, depending on the kinds of empirical data that inform the debates (see Table 1).

Biology, Table 1 The four types of debates on biological evolution

Types of debate/ debaters	Based on or implicating	
	Macroscopic data	Microscopic data
I	Yes	No
II	No	Yes
III	Yes	Yes
IV	No	No

One utility of the typology given in Table 1 may be that it provides us with a “selection rule” stating that no two debaters of different types can reach a fruitful conclusion or that, when the debaters belong to two different types, it is impossible for them to reach a fruitful consensus.

All the debates on evolution before molecular biology was born around the mid-twentieth century belong to what is referred to as the type I debates in Table 1. The evolution-creation debates that began in Darwin’s days and continue today are mostly between scientists (types II or III) and some Christians acting as type I or even type IV debaters. Macroscopic data on evolution are of such a nature that they may not be able to provide an objective basis for rationally resolving any type I evolutionary debates. In contrast, new kinds of debates, here called types II and III, arose as the results of analyzing experimental data on the molecular biology of inheritance that began most notably with the discovery of DNA double helix by Watson and Crick (1953) and the subsequent discovery of the genetic code, and these debates are waged among biologists and other scientists who are types II and III debaters who are likely to reach fruitful results.

Type II debates arise when a given set of molecular data obtained from biological experiments can be interpreted in terms of more than one molecular mechanism, for example, the relative importance of random mutations vs. nonrandom recombinations in determining the genotypic variations of an organism. A molecular mechanism is defined here as a set of molecular processes that is thought to underlie a given empirical observation. Type III evolutionary debates are concerned with the question as to how the macroscopic and microscopic aspects

of biological evolution can be bridged. Similar problems of connecting the macroscopic and microscopic events were encountered and successfully resolved in simpler sciences, physics, and chemistry in the past by introducing major novel concepts such as the concept of quantum of action in physics and the periodic table in chemistry. Similarly, connecting the macroscopic Darwinian theory of evolution and the microscopic theories of molecular and cell biology may require invoking one or more new concepts (e.g., conformons, the cell force; see above). Finally, for a logical completeness, it is necessary to include type IV debates on evolution that are based neither on macroscopic (e.g., fossil records) nor microscopic empirical data (e.g., coevolution of DNA sequences among different species) but only on religious beliefs such as found in the Old and New Testaments of Christianity or in other world religious writings.

Biology of Aesthetics

Bjørn Grinde

Department of Mental Health, Norwegian
Institute of Public Health, Nydalen, Oslo,
Norway

Description

Somewhere along our evolutionary path, the human lineage developed an obsession with beauty in sounds and objects. The clue to understand the biology behind this phenomenon lies in a dictionary definition of beauty: “A quality that gives pleasure to the mind.” Humans are equipped with several types of senses, but only the two based on eyes and ears transmit signals associated with aesthetics. Thus, the pertinent

question when it comes to understanding the biology of aesthetics is “Why are certain visual and auditory stimuli processed in a way that gives us pleasure?”

The brain receives a continuous flow of sensory information. Most signals are neutral, some may be repulsive, but a considerable variety of signals have the potential of eliciting some sort of pleasure. The term aesthetics within biology, however, is generally limited to stimuli derived from sounds or objects produced with the aim of eliciting a positive experience. In other words, aesthetics is about man-made creations that offer pleasure based on our auditory and visual senses.

Evolution did not give us eyes and ears for the purpose of idle pleasures. They are part of a survival kit. Looking at a painting or listening to music is unlikely to help you survive, yet people spend a fair amount of time doing just that. This entry tries to explain why. For a more comprehensive text, see (Grinde 2012).

The Many Components of Art

A concern for aesthetics appears to be a universal feature among human cultures, strongly suggesting that there are innate mechanisms behind. The evolutionary perspective may, therefore, help explain why we care about beauty, and, possibly, suggest what aspects of music and art that tingle our brain in a way that causes satisfaction.

First, one needs to dissect what art is about, that is, to distinguish between aesthetic elements and other aspects. Aesthetics serves several cultural functions, such as communication with God, and influencing people’s political ideas. Moreover, art has obvious economic aspects, not just in the value of pieces of art, but also in the use of aesthetics to sell products. Another highly relevant feature is the potential that art has in offering status to those with relevant skills – a point that is particularly relevant when it comes to attracting a mate.

Another way of dissecting art is to distinguish between pure aesthetic elements and experiences based on the associative content; for example,

a love song may stimulate some of the positive feelings involved in love, and a painting of a baby may warm the heart of adults.

This entry focuses on the elements that add what may be referred to as *aesthetic value*. It is assumed that these elements operate independent of cultural implications and associations involved. This statement is backed by the observation that people tend to agree upon what is good, or not so good, in art derived from different cultures. It implies that there are vaguely definable aesthetic rules, employed by the artists, which add a particular artistic quality. These rules, or elements, are what we look for when distinguishing between a bowl with solely functional value and a bowl with added aesthetic value; or cherished music compared to just noise.

While many aspects of art depend on particular individual or cultural parameters, the underlying aesthetic elements appear to rely on innate features of the human mind. These more intuitive elements are not necessarily the most important, but they are the focus of this entry. Other aspects of art, not the least its function in mate choice, have obvious biological implications, but they are considered less relevant when discussing aesthetics.

Brain Rewards

The intuitive aesthetic elements are a question of what sort of visual or auditory signals that are likely to be processed by the brain in a way that gives the observer a positive feeling. In order to appreciate this perspective, it is important to have a basal understanding of why the brain offers positive and negative experiences. As a general rule, feelings serve one of two functions: they either encourage or discourage particular types of behavior. Food taste good, so you eat. It hurts to burn your finger, so you avoid fire. In other words, feelings tend to come in two flavors: positive or negative. This is, of course, a simplified version of reality. In many instances, the value is less obvious and quite often it depends on the situation. Some people enjoy the thrill of a dangerous task, such as climbing a mountain, while others consider it a totally unpleasant

affair. Still this bipolar view of brain instigation is useful for the present purpose. Thus, I shall use the terms brain rewards and brain punishments to signify sensations experienced as respectively positive and negative.

Some further comments are called for. Employing your brain or body to do what they are designed for is generally positive, in the sense that it is good for your genes, and therefore, connected with rewards. This implies that even sadness may “feel good” because it is a reaction that under certain circumstances serves you well. Signs of sadness may, for example, elicit help from others. Several Hollywood productions testify to the potential value of sorrow – people flock to movies that make them cry.

Another important point to note is that reward-type mechanisms for directing behavior are not necessarily adaptive in the situation we live in at present. The reward of an orgasm feels good regardless of contraceptives. For the genes, unproductive sex can be seen as a waste of time, but the genes did not foresee the invention of contraceptives. Likewise, adding aesthetic value to an object or a work of art does not necessarily give any evolutionary advantage. The essential feature of aesthetics is to evoke feelings perceived as positive. The feelings do not need to be cheerful, neither is any engagement in art necessarily adaptive. The brain offers “rewards” because directing your attention to particular types of sensory input was adaptive at some point in our evolutionary history.

Visual Aesthetics

Our ancestors began to walk upright some 3–4 million years ago, thereby freeing their hands for more advanced manipulation of tools. Tools can be of obvious importance for survival, the surprising part is that at some point people started to add beauty to the objects. Today we have moved one step further: We create objects of art with no apparent practical value.

The first obvious signs of this propensity, in the form of cave paintings and the production of figurines, date back some 40,000 years. However,

archaeologists have discovered signs of similar behavior at least 100,000 years ago, in the form of presumed shell necklaces and the use of pigments. Most likely artistic behavior goes back much further, but direct evidence is difficult to find due to the lack of lasting objects. In fact, even chimpanzees appear to take delight in producing art – which is not surprising, as the aesthetic elements to be discussed below presumably have a long evolutionary history (see Grinde 1996).

Elements of Visual Aesthetics

Balance and Symmetry

One of the few rules of aesthetics that has won a certain acceptance is the principle stating that the main motif in a picture should divide the canvas in a ratio of approximately 3:5. What the principle suggests is that placing an object in the middle is boring, while placing it too far to one side produces an unbalanced appearance. The ratio of 3:5 is supposedly the optimal compromise between these two undesirables. The disagreeable effect of the unbalanced picture is possibly connected with our fear of falling. Falling is not a common problem for an animal stationed on the ground, but our ancestors did at one point live in trees. Furthermore, even ground-dwelling animals would be conscious of the possibility that an unbalanced rock may roll. A dominant object on one side of a picture gives the unpleasant impression that this side is tilting unless a balance is added on the opposite side. On the other hand, we tend to cherish a bit of excitement. Thus, the choice is much a question of what sort of subconscious feelings the artist aims for: thrill or calmness. Both offer possible brain rewards.

In some cases, an exact balance may add particular value. Symmetry is appreciated. Perfect symmetry in a person's anatomy, or in a prey animal, is a sign of gene quality, which is to be desired. The positive value of symmetry in connection with aesthetics is most obvious in architecture. Many buildings considered to be great works of art have symmetrical features.

Color

Many plants offer nourishment to animals in exchange for helping their seeds. Tomatoes, for example, are meant to be eaten – the perfect start for the seeds of this plant is to end up in feces. In order to signal that the fruit is ready to be eaten, a conspicuous color is usually added. Animals have evolved the ability to respond accordingly. They have a visual system enabling them to spot ripe fruit. Fruits and berries are important for human sustenance. To induce us to find them, we presumably developed appropriate brain rewards, that is, an appreciation of colorful objects that contrast with the surroundings. I believe these rewards constitute an element in the biology of aesthetics. In line with this notion, we do indeed appear to prefer warm colors, such as red or yellow – particularly as opposed to brown. Ripe fruit is typically red or yellow, while feces, a substance to be avoided, are brown. Colors that are light and fresh tend to be considered pleasant while darker, and muddier, colors, particularly brownish or grayish, tend to be depressing. Humans thrive in daylight. However, as pointed out above, even sadness can be conceived as a positive sensation. Thus, the artist may very well create a great painting using dark brown rather than brilliant red.

Curiosity and Attention

Some animals are specialists. Cows, for example, concentrate their attention on a limited range of visual impressions, such as the quality of grass. Humans are quite the opposite. We are specialists in nonspecializing. We are stimulus-hungry and have an inclination to gather all sorts of information from our surroundings. Survival often depends on careful observation, such as finding the way, gathering food, and recognizing faces. Exploratory behavior is, therefore, connected with brain rewards. The term “boring” is used in aesthetics when there is not sufficient variation or novelty in a work of art. The object lacks sufficient detail to attract attention. On the other hand, complexity stimulates our curiosity and is, therefore, pleasing.

A too complex visual input may, however, prove adverse. The mind needs to find clues that

can help it organize the details. Thus, there should be a unity in the diversity. In the aesthetic tradition of the Chinese, there is a concept called “The rule of five,” referring to the limitations of the human attention span: The mind can without too much effort grasp five elements at a time. If too many unconnected elements are added, the impact may be stressful. As a rule of thumb, the complexity should not move beyond the attention potential of the human brain.

Depth and Movement

Binocular vision is typical for primates. This feature is probably connected with the visual requirements of living in trees. Moving from branch to branch demands an accurate ability to measure distances. In order to take full advantage of the various potentials of the brain, we need practice. Children are encouraged to practice by participating in play activities. The purpose of play is to learn tasks that the brain has a rudimentary potential for performing, but which yet require further training. The brain rewards us for developing our potentials. Our ability to measure depth and calculate movements requires practice. We may, therefore, be rewarded for processing visual input relevant to this task.

A typical criticism of amateur paintings is that they appear flat. We appreciate a painter who manages to create the perception of depth. It is possible to lure the brain into perceiving motion by adding dots of different colors, but the same light intensity. Furthermore, a picture may contain lines that the eyes are induced to follow, and thus offer the viewer a sense of movement.

Functionality

The idea that the functional is also visually attractive was particularly influential on architecture in the 1930s. A central doctrine then was that form should follow function. A related idea is that art should try to perfect nature. Beauty has been described as a “comprehensible representation of the perfect.”

There are obvious reasons why looking for functionality and perfection should be connected with a reward. Consuming rotten food may be

dangerous, whereas eating the best specimens keeps you healthy. Moreover, it is important to recognize the functional qualities of tools. Receiving a pleasant sensation when viewing the right objects helps the individual to distinguish good from bad, and stimulates us to try to obtain the better items.

Art as Hedonism

The above list of elements is not necessarily exhaustive. The focus has been on presenting a way of understanding aesthetics. The list includes what I believe to be the more important factors. Our visual system, including the accompanying reward mechanisms, was developed for viewing nature, not artificial objects. The attributes of our vision, as well as the characteristics of nature, may guide us in an attempt to find and utilize aesthetic elements.

Obviously, there are numerous ways of eliciting rewards. Thus, the theory presented here does not restrict the artist to narrow rules. The present understanding of aesthetics is related to a dominant philosophy of art sometimes referred to as the *hedonist school*. Its central idea is that aesthetics is about creating images that induce pleasure. The biological model adds substance to this theory. It agrees with the central notion, but by using the word “pleasure” in a broader sense, the model helps resolve a paradox of the hedonist school: Why so many of the great works of art reflect sadness and tragedy? As explained above, the feeling of sadness is not necessarily negative.

Auditory Aesthetics

Music can arouse a surprisingly intense emotional response. The biological approach to understanding the human mind may offer an explanation.

Again, the answer depends on insight into why certain sensory stimuli are processed in a way that engaged reward-type nervous circuits. Although musical appreciation is clearly influenced by

nurture, several arguments favor the notion that the appreciation of music is an innate trait. One line of evidence for a genetic influence is the universality of musical appreciation. Most cultures make use of music, if not with advanced instruments, in the form of song and rhythm. Playable flutes that are almost 9,000 years old have been found in China, and a piece of bone discovered at a Neanderthal site had holes drilled into the hollow part, suggesting that even they made flutes. The observation that musical appreciation apparently arises spontaneously in children offers further evidence, and so does the powerful effect music has on the human mind. The Neanderthal lineage diverged from the lineage leading to present-day humans more than half a million years ago. Thus, the ability to appreciate music may have been present in hominids for a long time (for further reading, see Grinde, 2000).

The Language Connection

Accepting that our passion for music is based on an innate tendency, the question is: Why is the human brain designed to connect certain forms of auditory signals with pleasurable sensations? In other words, what sort of evolutionary forces carved this tendency into the human mind?

Oral language is the most obvious advantage associated with complex sounds. A possible evolutionary connection between language and music has been discussed by several authors, starting with Darwin in his “Descent of Man.” I shall expand on this connection, in an attempt to develop a coherent theory for the evolution of musical appreciation. The language connection is the pivotal element, but other forces are presumably also involved.

The way human infants learn language is different from the way birds learn to vocalize. The sound-producing capacity of most birds tends to be fixed. Some are able to learn by imitation and to elaborate on themes, thus creating both dialects and individual signatures, but their song is mainly hard-wired. Humans are born with an innate capacity for language, but this is only a template; extensive practice is required in

order to learn to produce and decipher language. Physical play is necessary for infants to develop the nerve circuitry required for muscular coordination. Focusing the mind on the production and interpretation of sounds is presumably adaptive behavior because it helps develop the nerve circuitry required for language. As such, this activity should be coupled with positive sensations.

According to this hypothesis, our appreciation for music was designed by evolution primarily in order to improve brain structures involved in language. It might be argued that the hypothesis would predict that a preoccupation with music, as with other play behavior, should be associated with children. In response to that, it may be noted that even when the main circuitry has been established, the mind presumably continues to pay attention to sounds for two reasons: Firstly, as adults we may still need to exercise our sound-producing and interpreting capacity. Secondly, we are stimulated not just to improve our senses, but also to use them in exploratory behavior. Exploratory behavior, that is, taking an interest in our surroundings, may decrease upon ageing, but does not disappear.

The concept of agreeable sensations designed for the purpose of improving the capacity for oral communication, as well as for stimulating an interest in sounds, can help explain music but then why are not all sounds equally pleasing? A further analysis is required to understand why we distinguish between noise and music – that is, we need to describe the features that cause auditory signals to be pleasing.

Elements of Auditory Aesthetics

Complexity and Coherence

As in the case of visual art, a certain complexity of sounds presumably has a positive effect on the listener. A single, pure tone is not that interesting to explore. A measure of intricacy is required to excite human curiosity. Sounds that are too complex, however, tend to be overwhelming. We presumably prefer some sort of coherence, that is, a principle that connects the various sounds and make them comprehensible.

Purity and Harmony

The tendency to prefer pure sounds is a central element in the enjoyment of music, and a possible consequence of the language connection. The preference for purity and consonance appears to be innate. One reason why these qualities are favored may be because they enhance oral communication. The capacity to produce pure sounds is most advanced in animals in which auditory signals are the prominent form of communication, such as songbirds and whales. A pure tone presumably carries further, and although language typically includes a mixture of relatively pure (vowels) and dissonant (consonants) sounds, harmony is expected to reduce ambiguity. The brain centers involved in the production and processing of sounds are probably predisposed to prefer sounds with suitable qualities.

Some languages are referred to as tone languages; that is, the meaning of a particular sound depends on the pitch. Speakers of these languages appear to be more able to recognize variations in pitch compared to speakers of non-tonal languages. It is conceivable that the first human languages were more like song, or at least depended on pitch, which would lead to an augmented interest in this aspect of sounds.

Temporal Patterning and the Human Touch

A main feature of human language, as opposed to oral communication in apes, is the importance of the temporal patterning of sounds. Single sounds are in most cases not sufficient to convey meaning, whereas when put together in a sequence they form words and sentences. Temporal patterning is equally important in music – if the tones are not in some way tied together sequentially, people are unlikely to show appreciation.

The temporal patterning is related to what the musical literature refers to as melody. It is conceivable that music requires similarities to language, such as complexity and melody, in order to be valued, because only then does it utilize the brain resources involved in processing spoken words.

Another element in the appreciation of sounds, as in visual arts, is the communicative aspect. Humans seek to gain knowledge about other individuals as part of our social nature. When a

person creates sounds, we tend to search for a message, or at least we expect that something about that person's emotional life can be inferred. A voice satisfies this criterion, the same goes for an instrument in the hands of a skilled musician, while it is difficult to program a computer to display emotion. In other words, the complexity should have a human flavor. It is interesting to note that people tend to agree, at least to some extent, on what emotions a given sequence of music reflects.

Safe and Relaxing Sounds

The appreciation of music depends on a variety of qualities of sounds, the language connection does not necessarily explain them all. Music can have a relaxing effect not only on humans, but on animals as well.

One possible explanation for the relaxing effect is that music is continuous and rhythmical. In a natural environment, danger tends to be accompanied by sudden, unexpected sounds. A background of constant noise suggests peaceful conditions; discontinuous sounds demand more attention. Even soft discontinuous sounds that we consciously realize do not signal danger can be disturbing, for example, the dripping of a leaky tap. A continuous sound, particularly one that is judged to be safe, relaxes the brain. As to the soothing effect on humans, it may also be pointed out that music presumably is intuitively understood to be man-made, and as such normally not related to dangerous situations.

Rhythm

One of the most characteristic features of music is rhythm. In tribal music, rhythm instruments are often the main element, but even elaborate music seems to require rhythm in order to be appreciated. The rare cases of experimental music without a beat have, as expected, not enjoyed commercial success. Rhythm is probably appreciated because it helps us organize the sound, and because it is a comforting feature. The comfort can be related to the absence of danger associated with rhythmic sounds, but also to a resemblance to the pulse of the mother's heart imprinted prenatally. Newborns appreciate sound in the form of voices, vocal music, or heartbeats.

The Chill

The above suggestions may explain a general appreciation for music, yet the emotional response is sometimes more overwhelming than what would be anticipated. Particular passages can generate an intense pleasurable experience described as a chill or a thrill.

It is not an expected evolutionary strategy to encourage a certain type of behavior in excess of what is adaptive. A person who is preoccupied with song or music pays less attention to other tasks or to possible dangers. For example, if you are engrossed in singing you are unlikely to detect an approaching predator. Thus the rewards associated with sounds should not divert our attention to a greater extent than what the contribution to survival suggests. The chill appears to be excessive encouragement.

Certain qualities of music that tend to produce chills point toward a possible explanation. Research suggests that chills are evoked more often by sad music than by happy music, by familiar music rather than an unknown piece, and intense passages, such as crescendos, are particularly chilling. Chills are more commonly experienced by women than by men. It is conceivable that chills hook directly onto the brain's primitive emotional circuits; more specifically, that music has some sort of relationship with the call of an infant crying for its mother. Separation calls are expected to evoke powerful feelings in parents – especially in mothers. Human separation calls have properties related to chill-producing sounds: the cry of a baby is at once intense, familiar, and sad. Long before the development of language, the genes had presumably designed the brain to offer ample rewards to ensure attentiveness to the call of infants. It is possible that a chill is an accidental sensation evoked when music happens to approach the sounds we are programmed to react to as caregivers.

However, it is also conceivable that a chill can be explained by the way evolution tends to utilize structures already present for novel purposes, as exemplified by the way legs evolved from the fins of fish. The need for positive sensations to encourage the processing and production of

sounds, which I suggest appeared as a consequence of the introduction of language, may have triggered evolution to recruit the emotional pathways associated with parents' attention to the cries of their babies.

Sexual Selection

An artist may feel that reducing aesthetics to an innate trait does not do either music or art justice. It is important to stress that the biological approach reflects only one of several possible perspectives relevant to the understanding of art. Moreover, in present society art has gained a "life of its own," partly independent of our innate preferences for particular qualities.

The suggested elements, and concomitant rewards, promote a preoccupation with certain types of sounds and visual stimuli. Obviously, the particular taste of an individual is governed by personal and cultural traits. Thus, the observation that the same music or painting may produce pleasure in one person and discomfort in another does not contradict the suggested aesthetic elements.

It was pointed out already that art serves several cultural functions, such as communication with both humans and spirits. It is possible that these functions contributed to the evolution of our innate preoccupation with art. Communication involves obtaining attention. However, both attention and communication may be achieved without adding beauty. A traffic sign is perfectly designed for attracting attention, yet few would treasure it as a work of art. Paintings, on the contrary, are sometimes very subtle and quiet. Furthermore, much of the art produced, such as that of children or amateurs, is apparently made solely for the satisfaction of the creator, and not for communicating with others. The greatest works of art are probably produced when aesthetic elements are used to enhance the communicative content. The aesthetic rewards are then added to associative rewards, creating a particularly strong impression.

It is also likely that sexual selection spurred the evolution of our aesthetic disposition; that is,

mate choice may have depended to some extent on musical and visual artistic abilities. Most of the advanced acoustic signals in nature are courtship signals. It is easy to imagine that competence in singing, or in following a rhythm, has improved the odds of success in a human courtship situation. The theory would help explain why love is the most popular theme for songs. Skill in decorating the body may have served a similar purpose.

Although cultural functions, particularly in terms of sexual display, probably contributed to the evolution of aesthetic appreciation, it seems unlikely that they represent the primary mover. I believe the aesthetic elements of the type described in this entry preceded possible social benefits. Sexual selection tends to expand particular features, among the more famous are the peacock's feathers, but generally the feature to be expanded was present before sexual selection started using it. In the absence of the aesthetic elements, the other functions of art would probably not have emerged.

For the Service of Life Quality

The life of dogs depends on a keen sense of smell. Dogs are unlikely to insist on going to a concert, or to an art exhibition, but they certainly would appreciate a "gallery" where they can sniff interesting odors.

Compared to dogs, we are expected to derive more pleasure from auditory and visual signals, and less from olfactory signals, simply because the auditory and visual signals are more important for human survival. Present music and art are designed to hit pleasure circuitries in the brain with maximum power. The artist accentuates the elements capable of stimulating brain rewards. That is, they offer exaggerated stimuli akin to the way a nesting bird will prefer a plastic egg if it is bigger than the real egg.

The role of art in present society is far from being adaptive in a biological sense. Then again, there is no reason why it should be. It seems more rational to define the purpose of life as improving life quality, rather than maximizing procreation.

The term *Darwinian Happiness* offers an expansion of this way of looking at quality of life. The various reward mechanisms activated by aesthetics offer an excellent strategy for happiness (Grinde, 2012). Artists, who are capable of finding novel ways of hitting the relevant rewards, should be valued.

What Does Biology Have to do with Religion?

Although it would be understandable for someone to ask, “What does biology have to do with religion?” the answer is easily given. Biology is the study of life or of living organisms. Humans are living organisms. Humans engage in religious behavior. In fact, except in some modern industrialized Western societies that have been secularizing for the past few centuries, religious behavior has been as much of a species-characteristic trait of human beings as the way we walk, talk, smile, and cry. It is easier for biology to concentrate on religious behavior rather than the subjective aspects of religious experience if for no other reason religious behavior is observable. However, biology has also modestly contributed something to our understanding of certain aspects of religious subjectivity by a new field of functional brain scanning, sometimes called “neurotheology,” in which areas of brain that are metabolically active during such things as prayer and feelings of transcendence can be studied (Newberg et al. 2001).

Ways of Studying Religious Behavior Biologically

Most biological studies on religion address religious behavior, looking at its evolutionary history, its development in the lifetime of the individual, its proximate causal mechanisms, and whether exhibiting it increases one’s survival and reproductive success. These are the four areas of investigation that are used in trying to understand the biology of any behavior, a method suggested many years ago by behavioral biologist Niko Tinbergen (Tinbergen 1951).

Literature on Biology and Religion

The first book to specifically address biology in reference to religion was Alister Hardy’s *The Biology of God: A Scientist’s Study of Man the Religious Animal* (1976). This was followed

by *The Biology of Religion* by Reynolds and Tanner (1983). In the last several years, two edited volumes have addressed the biology of religious behavior (Feierman 2009; Volland and Schiefenöhovel 2009).

Assortative (Preferential) Mating and Religions

Because in modern industrialized societies people tend to marry persons of their same religion with a greater than chance probabilities, religions can also be thought of what in biology would be called a “breeding (or mating) population.” That of course has lots of biological consequences. There are very few religions that do not have rules and regulations regarding the sexual behavior of their members. And they do that for good reason, given what appears to be one of religions functions.

Religion, Celibacy, and Biology

Religious celibacy as one more relationship between biology and religion. Religious all-male communities, as seen in Buddhism and Roman Catholicism, are somewhat “natural,” as they are similar to nonreproducing social groups or bands of nonhuman, normatively social, male primate species. No normatively social primate species has been described in which females form nonreproducing bands save human beings in terms of Roman Catholic women religious communities, an anomaly in primatology for certain. Lone males, which could be considered the current biological characterization of diocesan Roman Catholic priests, have much less precedence in primatology in a normatively social species, such as our own.

Disease and Religion

There is another rather interesting relationship between biology and religion, which has to do with disease in general and infectious disease in

particular. In human religious history, shamans and medicine men were the first religious practitioners. One of their primary roles was the treatment of various diseases, which they accomplished primarily through ritual.

Religion has another relationship to infectious disease. In traditional tribal societies religious diversity (i.e., more religions per area) correlates positively with the area’s pathogen prevalence, which means that there is more density of tribal religions in the parasite-rich tropics compared to temperate areas (Fincher and Thornhill 2008). Religious differences, often phrased as differences over religious beliefs, are a known cause of, and perhaps even a mechanism of, human tribal groups dividing (Price 2009).

Survival, Reproductive Success, and Religion

In advanced industrialized societies today, and for reasons unknown, persons of faith, who are practicing religious behavior, also have better survival and reproductive success than their secularist neighbors (Bloom 2009), a correlation with lots of biological significance.

Biology, Theoretical

Michał Kurzynski
Faculty of Physics, Adam Mickiewicz
University, Poznań, Poland

The meaning of the word “theoretical biology” depends on what we understand by the word “theory.” Here, we assume that a theory is a compact set of concepts and principles able to unify and explain a certain class of facts, in this case related to the phenomenon of life. In exemplary fashion, the conceptual apparatus used is abstractive enough to be formalized in terms of mathematics. In the course of the history of science, we can distinguish only a few systems of views that are worth to be termed the biological theory. Some of these are reviewed below in the order of their original formulation.

Circulation Theory. In a sense, this theory goes back to traditional Chinese medicine and a concept of Zang Fu including five pairs of organs connected by five “fluids,” among which

we distinguish Xue (blood) (Ross 1989). Contrary to Western medicine, the Eastern, Chinese medicine was more theoretical than experimental, though both have finally the practical purposes. It was William Harvey (1628) who, underpinning the mechanistic, “European” methodology of Rene Descartes, described the human circulatory system as composed of heart, the pump, and the vascular system of arteries and veins. Later on Marcello Malpighi discovered capillaries connecting arteries and veins, and the whole human circulatory system has been divided into the closed cardiovascular system, transporting blood, and the open lymphatic system, transporting lymph (Wright 2012). The physical theory of hydrodynamics can be applied for description and explanation of the circulatory system action, using such notions as the velocity and the pressure fields, and transport through semipermeable membranes (Elad and Einav 2003). The theory explains the flow and diffusion of gases, electrolytes, nutrients, signaling molecules, antibodies, and the whole movable cells. Recently, the system of capillaries has been described in terms of fractal networks (Pereira 2010). Contrary to the circulatory system, the nervous system of higher animals cannot be directly described in physical terms, as the nerve conduction is not a simple electric conduction. A special nonphysical theory of neural networks has been developed, but there are still too many questions involved to treat it as a complete biological theory.

Cell Theory. The cell was first observed and described by Robert Hooke (1665) and Antonie van Leeuwenhoek (1674), who were among the constructors of the microscope. Almost two centuries of continuous improving, the optical microscopic technique entitled Theodor Schwann and Matthias Schleiden (1839), and Rudolph Virchow (1855) to formulate a theory the main theses of which can be expressed in the following three statements (Harris 2000):

- The cell is the most basic unit of life.
- All living individuals are either unicellular or composed of many cells.
- All cells come either from division of preexisting cells or by conjugation of two generative cells.

We distinguish simple prokaryotic cells from much more complex eukaryotic cells, which probably originated from the symbiotic conjugation of several prokaryotic cells of different kinds. The origin of the first prokaryotic cell is a separate problem. It is a matter of definition of life whether viruses are alive or not.

The cell theory, in natural way, divides mathematical modeling of the biological phenomena onto two levels. A subcellular organization is the object of cellular biology that deals with structure, dynamics, and function of a single cell (Lodish et al. 2000, Chap. 1). Two complementary theoretical approaches to cellular biology have been developed, namely, the reductionist molecular biology (Lodish et al. 2000) and the holistic systems biology (Palsson 2006). Molecular biology uses the theoretical apparatus of molecular biophysics and biochemistry. Systems biology on the other hand starts from an informational content of the cell genome and uses the mathematical apparatus of the theory of evolution (see below). A supracellular organization of living matter is the object of developmental biology (Wolpert 2011). It deals with the cell differentiation and the origin of higher levels of organization – tissues, organs, and, in particular, the circulatory system. The theory of morphogenesis initiated by Alan Turing (1952) uses mathematical language of partial differential equations describing a system of chemical reactions coupled to processes of spatial diffusion of controlling agents (Harrison 2005).

Theory of Inheritance (Smith 1997, Chap. 3). The fundamentals of this theory were formulated by Gregor Mendel (1865) who investigated inheritance of discrete traits of organisms called genes. Each gene can occur in different versions called alleles. The organism inherits one allele from each parent; hence, each gene is represented twice. Some alleles are dominant and some recessive, and this fact determines the corresponding trait. Forgotten at first, Mendel's work was rediscovered at the beginning of twentieth century by Hugo de Vries (1901), who introduced the concept of mutation and mutant; William Bateson (1905), who coined the word "genetics"; and Wilhelm Johannsen (1909), who introduced

the concepts of genotype as the complete set of all the genes of a given organism, and phenotype as the complete set of all the observable traits. Mendel's laws of inheritance of a single trait were generalized to whole phenotype by Godfrey Hardy and Wilhelm Weinberg (1908). Probability theory and mathematical statistics appeared ideal tools for predicting inherited traits (Edwards 2000).

Introduction of genetics onto the cellular level was done by Thomas Hunt Morgan (1910) who argued that genes are located on chromosomes at definite positions referred to by him as loci. Variation in heredity is not entirely due to gene mutations but to gene recombination in the process of crossing-over of homologous pairs of chromosomes. Linear order of genes along individual chromosomes makes probabilities of occurrence and variation of the corresponding alleles mutually correlated.

However, the greatest turning point was introduction of genetics onto the molecular level. It was done by Oswald Avery and coworkers in 1944, when the genetic information carrier was identified with DNA. The DNA double helix model discovered by James Watson and Francis Crick in 1953 explains the genetic information replication, point mutations, and the crossing-over as well (Lodish et al. 2000). The knowledge of genomes, the sets of all genes along the DNA chain, from viruses through yeast to men (2003), started the new era of theoretical biology. Although mathematically inclined researchers hope to ultimately achieve mathematical analyses of genetic information included at the DNA (genomics), mRNA (transcriptomics), and protein (proteomics) levels (Palsson 2006), these omics may be too complex to be so analyzed and require utilizing additional nonmathematical tools including linguistics, semiotics (the science of signs), and algorithms (Ji 2012).

Theory of Evolution (Smith 1997; Bowler 1989). The idea that evolution is driven by natural selection comes from Charles Darwin (1859). His reasoning can be summarized in three sentences.

- Due to heredity, offspring is similar to parents.
- However, small variations during reproduction occur, giving rise to different fitness to

habitat of particular individuals in the next generation.

- There is a surplus in reproduction with respect to resources; thus, only the fittest can survive.

The process results in accumulation of gradual changes in subsequent generations which can culminate in the emergence of new species. The theory explained exclusivity and hierarchy of the biological taxonomy. Darwin's view was very revolutionary. Unfortunately, two of its main propagators in the second half of nineteenth century hampered rather than helped the future triumph. The analogy between phylogenesis and ontogenesis proposed by Ernst Haeckel was rather shallow, whereas the idea of Herbert Spencer to generalize survival of the fittest to the human society (Social Darwinism, the "struggle for life") appeared simply dangerous (Bowler 1989).

A weak point of Darwin's original theory was the lack of the knowledge concerning the heredity mechanism. The rediscovery of Mendel's theory of heredity at the beginning of twentieth century did not result directly in combination of the both theories. Even Thomas H. Morgan doubted the theory of evolution, asserting that all individuals have the same "wild" genotype because all the mutants are eliminated by natural selection. An actual combination of Darwinian evolution by natural selection with Mendelian inheritance was initiated in Soviet Union by Sergei Chetverikov (1926) and in Great Britain by Julian Huxley (1927), a grandson of Thomas H. Huxley, a famous partaker of the first debate on the theory of evolution. Ronald A. Fisher, John B. S. Haldane, and Sewall Wright (1931) introduced the concept of genetic drift within populations, which together with natural selection and gene flow between populations are considered by the modern evolutionary synthesis, formulated by Ernst Mayr (1942) as the three main mechanisms of evolution (Bowler 1989).

The objects of mathematical models of the theory of evolution are populations, the more or less isolated collections of individuals of the same species. The numerical force of individual populations and its variation in time are considered by population dynamics. In the course of

development of this theory, let us mention the logistic model by Pierre-Francois Verhulst, the oscillating predator-prey model by Alfred J. Lotka and Vito Volterra, the autocatalytic hypercycle model of Manfred Eigen and Peter Schuster (1979), and the evolving networks model by Sanjay Jain and Sandeep Krishna (1998) (Sneppen and Zocchi 2005).

On a deeper level, the population is represented by a probability distribution in a genome space. On assuming that the evolution is a Markov process, the genetic drift can be modeled by diffusion in the genome space in which the selection is determined by some fitness landscape. Various landscapes have been proposed (Sneppen and Zocchi 2005). R. A. Fisher (1930) in his simple theory of evolution assumed a constant gradient of fitness which caused the initial distribution to move steadily to higher fitness. There was no mechanism of speciation. Such a mechanism was proposed by Sewall Wright (1945) who envisioned that barriers between local maxima of fitness to be quickly overcome. The evolution was treated as an optimization process, which later on found an application in numerical techniques of the evolutionary algorithms. Quite opposite mechanism of speciation was proposed by Motoo Kimura (1983) in the neutral theory of evolution. The fitness landscape is flat, but there are many bottlenecks in reaching particular regions in the genome space by unfitted genetic drift. Yet another mechanism of speciation, related to localization in a random fitness landscape, was proposed by Manfred Eigen (1971, 1989) (Eigen et al. 1989).

A turning point in the theory of evolution appeared in the concept of punctuated equilibria formulated by Niles Eldredge and Stephen Gould (1972) (Gould 2007). Basing on a large material of fossil records, these authors argued that, contrary to original gradualistic approach of Darwin, evolution did not occur uniformly but in jumps between shorter or longer periods of equilibria of the duration time distributed approximately according to a power law. The diffusion theory of genetic drift was too weak to explain this phenomenon and so did the theory of random

Boolean networks considered by Stuart Kauffman (1969). Only cellular automata formalism applied by Per Bak and Kim Sneppen (1993) and that of evolving scale-free networks applied by Sanjay Jain and Sandeep Krishna (2001) succeeded in explaining the phenomenon which is now known as self-organized criticality (Sneppen and Zocchi 2005).

Biology and Medicine. The notion of “theory” we assumed opposes the notion of “experiment”. However, very often the word “theory” is used in another sense, as opposing the word “practice.” This is a rule in the case of medicine, an art rather than a science, for which biology is the scientific background. Three theories understood in the second meaning influence strongly the contemporary medicine. *Germ Theory of Infectious Diseases*, commonly linked with the names of Louis Pasteur and Robert Koch in the 1870 s, attributes their cause to the action of pathogenic microbial agents. Now we know that these can be prions, viruses, bacteria, fungi, protozoa, or multicellular parasites as well (Waller 2004). *Receptor Theory of Pharmacology*, foundations of which are due to Paul Ehrlich in the beginning of twentieth century, relates action of drugs with inhibition or activation of particular cell receptors of either the patient or the pathogenic organism (Maehle et al. 2002). And the most recent *Gene Theory of Carcinogenesis*, for which the names of J. Michael Bishop and Harold E. Varmus in the 1980s seem to be the most meritorious, relates malignant transformation of a normal cell with mutation of some genes. These can be “proto-oncogenes,” whose products participate in cellular growth-controlling pathways or tumor-suppressor genes coding proteins that stop the cell cycle if its previous step has occurred incorrectly or if DNA has been damaged (Lodish et al. 2000). All the three medical theories refer to fundamental fields of biology, mainly cellular biology and immunology, in line with the disciplines discussed in more details above.

Biology and Physics. Certainly, all the biological organisms are simultaneously physical systems and thus can be described and explained in terms of physics. The problem of the reduction of biology to physics depends strongly on meanings

given by various investigators to particular concepts and it is not my aim to discuss it here. I only feel that some life processes can be better explained in terms of theoretical physics and others, in terms of theoretical biology. It is worth pointing out the main difference between the methodology of physicists and biologists which seems to appear when comparing the ways of thinking of the two greatest theorists in both sciences, Isaac Newton and Charles Darwin. For the physicist Newton, the most important were common properties of all the bodies of the Solar System. His splendid idea was to treat all of them as points differing only in masses and influenced by the same gravitational forces. For the biologist Darwin, in contrast, the most important were numerous differences between the individuals, because exactly these differences were the object of natural selection.

The physical and the biological ways of applying statistics and the probability theory are different. The physical approach proves correct if the number of individuals is much greater than the number of possible internal states of each individual, and the biological approach proves correct if the number of the possible internal states is greater than the number of individuals (Sneppen and Zocchi 2005). There is a strong experimental evidence that the native state of proteins and nucleic acids with an established primary (i.e., chemical) structure consists of an astronomical number of different conformational (i.e., spatial) substates with the spectrum of relaxation times to equilibrium comprising many orders of the magnitude (Kurzynski 2006). This raises the question, unanswered till now, as to whether the physical or the biological statistical approach is more correct in the description of various molecular processes involving such biomolecules. These include the DNA to RNA transcription, the protein folding, and the enzymatic catalysis as well.

Biome

Stanley N. Salthe

Department of Biological Sciences, Binghamton University, Binghamton, NY, USA

B

A biome is a particular local ecosystem with a name, like a river, beach, or forest in some actual geographic location. Examples would be Chesapeake Bay, the Adirondack Mountains, or the Sonoran Desert. They do not usually have clear boundaries.

Biopsychosocial Model

Kevin S. Masters

Department of Psychology, University of Colorado Denver, Denver, CO, USA

A way of conceptualizing health and illness that incorporates a systems approach and proposes that biological, psychological, social, and environmental factors are all equally important and must be simultaneously considered in order to gather a complete understanding of human

functioning. Further, it is not simply consideration of these factors (or levels, subsystems) as distinct parts of a whole that is crucial but rather it is the continuous interactions among and between these aspects of functioning that produces new emergent properties vital to understanding the vitality of the organism. Living organisms, such as humans, are open systems residing in a changing environment and material and energy are exchanged across the organism-environment boundary. As such, humans are actively involved with their environment in a reciprocal and interactive relationship. This model was most notably proposed by Engel in an article in the journal *Science* in 1977.

Semiotics

Up until twentieth-century semiotics, the study of sign processes (semiosis), that is, processes of communication and signification, has been concerned mainly with that unique sign system which is human language. When in 1963 the American linguist Thomas A. Sebeok suggested that the science of ethology did also in a sense belong to semiotics, namely, as *zoosemiotics*, the study of animal sign systems, very few of his colleagues were ready to follow him

(Sebeok 1963, 1979). The Cartesian divide between the sciences of nature and culture was, and to a large degree still is, a vital ingredient in the matrix of beliefs on which human and natural sciences alike are based. However, this privileging of human speech, as a different matter altogether than sign processes as they play out in natural systems (scents, roars, cries, alarm calls, animal tracks, fever, coughing, etc.), was challenged more than hundred years ago by the American scientist and philosopher Charles S. Peirce (1839–1914) and long before him by the churchman Augustine (354–430) who defined a sign as “anything perceived which makes something besides itself come into awareness” (quoted from Deely 2001, 221).

In Peirce’s semiotics, the sign only takes on its signhood in the actual act of interpretative activity. An alleged sign becomes a sign only to the extent it provokes the formation of an *interpretant* (see below) in a receptive system consisting in the drawing by the receptive system of a suitable relation between the alleged sign and its object, that is, the thing or concept to which the sign is taken to refer. In Peirce’s own terms, a sign is “something which stands to somebody for something in some respect or capacity.” Thus, to take a simple case, smoke is something that to a human observer stands for fire. Smoke, observer, and fire thus are connected through a *triadic sign relation* where the smoke takes the position of the *primary sign*, fire takes the position of the *object*, and brain processes in the human observer is seen as the *interpretant*. It is important to observe in this connection that when Peirce uses the term *somebody*, he is not necessarily, nor exclusively, referring to a human person. The Peircean *interpretant* is a general category that in no way is unique to the semiotic activity of human beings, but is defined rather through its position in the triadic logic of the sign relation. Neither should the *interpretant* therefore be confused with the distinctly different notion of an *interpreter*. Since the three elements, sign, object, and interpretant, may belong to various orders of reality as single objects, general classes, fictions, mental representations, physical impulses, biological events, human actions,

organic activities, or natural laws, what constitutes the sign relation in its logical form is the particular way in which this triad is bound together.

Now, returning to the example of smoke as a sign, we should notice that a baby will not know that smoke signifies fire; the baby's brain will not produce an interpretant relating smoke to fire, sign to object. Perhaps the baby will make a more simple interpretant, an icon, relating the smell of smoke to other previously experienced unpleasant sensations. In the world of signs, there is no unambiguous connection between a sign and a signified; it all depends on the receptive system and the context in which the interpretant is formed. A Peircean sign is therefore radically different from the concept of signal or information as used in biology or biochemistry as, for instance, when we talk about *transcription* and *translation* of genetic information. In spite of the semiotic nature of such terminology, biology does not ascribe any interpretative capacity to the cellular system where these processes take place. Rather such processes are understood as perfectly normal causal chains of processes to be exhaustively described in molecular terms. Thus, here and in countless other places, semiotic terminology is understood as only metaphorical, and it is assumed that in due time, they can be and will be reduced into the chemical and physical interactions that produce the effects or functions so labeled.

Biosemiotics

The introduction of a semiotic sign conception into scientific biology marks off the biosemiotic approach relative to its two parent disciplines, biology and semiotics (Sebeok and Umiker-Sebeok 1991; Hoffmeyer and Emmeche 1999; Favareau 2008). Biosemiotics studies the webs of sign processes as they occur in natural systems including the human body. As in other border disciplines, there are vivid and as yet unsettled discussions in the biosemiotic society concerning the exact delimitations relative to human cognitive processes, prebiotic processes, and artificial

life systems, respectively. Most students of biosemiotics take the cell to be the simplest system capable of genuine sign action, *semiosis*, but others subscribe to a more general view of semiosis in which semiosis may even be seen as inherent to our universe (*physiosemsiosis*). Regardless of which position one chooses on this question, it remains a challenging question for biosemiotics to explain how the full-blown semiotic activity of whole cells could possibly have evolved in the world. It has recently been suggested that rather than trying to determine a distinct borderline between semiotic and presemiotic or protosemiotic systems, one should apply the notion of an evolutionary threshold zone comprising a series of intermediate steps connecting asemiotic prebiotic systems to cellular semiotic systems (Kull et al. 2009).

A major distinction in biosemiotics has been drawn between so-called *endosemsiosis* referring to sign processes inside the body (the level of physiology and biochemistry) and *exosemsiosis*, that is, the sign processes that take place between organisms (the level of ethology and ecology). This endo-exo asymmetry is not always clear, however, since the concept of an individual is not itself clear-cut. Thus, to take an example, are the bacterial floras in our guts – without which we could not survive – made up of billions of distinct individuals or should it rather be seen as an integral part of our body so that the semiotic interactions of these bacteria with surface cells of the gastrointestinal tract are in fact endosemiotic and not exosemiotic?

In most cases the exo-endosemiotic distinction is quite convenient because it more or less follows the traditional division between disciplines, but it should be emphasized that the focal locus for biosemiotic analysis is the membrane. Biomembranes are semipermeable encapsulating structures canalizing a highly selective flow of chemicals across themselves. As such the membrane defines an asymmetry between an “inside” and an “outside” and a need for semiotic activity that connects the “outside world” to the “inside world” so as to permit the processes of the encapsulated system to help the system to deal appropriately with its surroundings. This kind of

connection forms the core of semiosis, the meaningful interpretation inside the system of the cues that reaches it from the environment. Multicellular organisms are not just covered by an external “membrane” in the form of skin (or chitin), but underneath this outer surface there are new membranes around organs, tissues, and individual cells, and inside cells we again find new membranes enveloping the cell organelles and filling up the cell volume with sack-formed structures such as the endoplasmic reticulum and Golgi apparatus. Thus, the total area of human biomembranes has been estimated to be some 30 km², and the maintenance of these extended areas of membranes is extremely costly as measured in metabolic energy.

Biosemiotics implies a major change in our conception of the role of the genetic material, the genome. Whereas the traditional view sees the developmental process and thus the phenotype as specified by the genetic setup of the organism, the genotype, biosemiotics makes us consider the overall process as one of interpretation rather than one of specification. The so-called genomic instructions are buried deeply inside the nuclei of individual cells that cannot for good reasons “know” which destiny or function in the adult organism they are “meant” to occupy, and the cellular apparatus is therefore utterly dependent on external “instructions” to tell it which genetic “instructions” to execute at each moment. External cues derived from neighboring cells or tissues, or from body glands, or “traveling cells” such as the cells of the immune system (lymphocytes) must be picked up by specific receptors located on or in the cell membrane and translated to intracellular processes (signal transduction) that interact with the protein complexes involved in transcription and translation of DNA as well as with the targeting of virgin proteins either to their final positions in the landscape of the cell or to excretion into extracellular space. At each step in this complex chain of linked processes, contextual factors may interact significantly with the outcome. Obviously the gene does not therefore in any ordinary sense of the word *determine* its own “reading,” and neither is it justified to talk about this process as

a *specification*. The process is best described as an interpretation with the implication that epigenetic and environmental factors must be seen as autonomous resources for ontogeny and phenotypic activity.

The fact that ontogeny is nevertheless very rigidly controlled has been taken as evidence for a dominating conservative mechanism linking the genetic setup to the functional phenotype through well-buffered chains of causal processes. In biosemiotics this explanation is supplemented or replaced by the notion of *semiotic scaffolding* (Hoffmeyer 2008): Processes at all levels of organismic function are controlled by semiotic interactions between components that incessantly adjust biochemical or physiological activity to changing situations. This network of semiotic controls establishes an enormously complex semiotic scaffolding for living systems. Semiotic scaffolding safeguards the optimal performance of organisms through semiotic interaction with cue elements which are characteristically present in dynamic situations. At the cellular level, semiotic scaffolding assures the proper integration of the digital coding system (the genome) into the myriad of analogical coding systems operative across the membranes of cells and cell organelles. The big advantage of this mechanism is that contrary to physically based interactions, semiotic interactions do not depend on any direct causal connection between the sign vehicle and the effect. Instead the two events are connected through the intervention of an interpretative response. The point is that in semiotic interactions, the causal machinery of the receptive system is itself in charge of producing the behavior and it thus only needs to acquire a sensitivity toward the sign as an inducing factor. The biochemical machinery underlying the response is not, therefore, restricted by any bonds deriving from the chemistry of the releasing sign. (Thus any volatile compound, pheromone, may be taken up and used by the evolutionary process as a vehicle for the sign process whereby a certain behavior is released in an given insect no matter what the exact chemistry of that pheromone is. This absence of a direct involvement of the sign in the biochemistry and physiology of behavior of

the receptive organism removes the hard limitations on causal mechanisms that would otherwise have to be obeyed.) When functionality first arises at a holistic level (e.g., the level of the tissue rather than the individual cells making up the tissue), any mechanism that will stabilize such functionality will be favored by selection, and in this context semiotic interaction patterns provides fast and versatile mechanisms for adaptations, mechanisms that depend on communication and “learning” (By learning at this level, we refer to cells’ acquisition of internal structural markers that reflect past events and influence future activity) rather than on genetic preformation.

The emergence of this sophisticated kind of stabilizing agency poses important challenges to our conceptions of evolution. In many cases semiotic scaffolding might work as a possible forerunner for natural selection: Due to its stabilizing capacity, semiotic scaffolding implies that natural selection may take routes that have been semiotically prepared for it rather than being directed by the haphazard events of fortunate chance mutations. Thus, biosemiotics holds that while genetic fixation may ultimately be the most secure mechanism for the stabilization of new traits or behaviors, such traits and behaviors were probably often initially stabilized through semiotic loops and thus kept functional for an indefinite period of generations allowing the time needed for the much slower mechanism of supportive genetic change to take place. Especially in the later states of evolution, such semiotic preparation is likely to have had an important influence on the actual outcome of selective solutions.

The introduction of a semiotic understanding has significant implications for ethology. Rather than reducing organismic behavior to inherited holistic lumps of reflexes, so-called instincts, biosemiotics suggests new subtle kinds of learning in situ associated with the establishment of semiotic scaffolding. The eventual appearance in big-brained animals such as birds and mammals of an experiential world would also be less of a mystery in the biosemiotic perspective than it is normally seen to be (and certainly not the

meaningless epiphenomenon that it is claimed to be by some philosophers). Since the sign itself is a pure relation (and cannot be identified with any of the three entities it brings together), biosemiotics necessarily accepts the reality of a causality that is directed (but not effectuated) by the influence of pure relations, which suggests the possibility that the experiential worlds might be analyzed as a realm of pure relations - interfaces - connecting environmental cues and sensomotoric brain modules to contextual patterns dependent on memory and intentions.

At the ecological level, biosemiotics requires us to extend our concept of an ecological niche to embrace the *semiotic niche*, that is, the totality of cues around the organism (or species) which the organism (or species) must necessarily be capable of interpreting wisely in order to survive and reproduce. One important aspect of the semiotic niche concerns the semiotic interactions between individuals from different species. Most notably among these, of course, stand predator-prey relations but just as significant perhaps is the range of interactive behaviors connected to symbiotic relations. When symbiosis is seen as a semiotically controlled kind of interspecific interaction, it becomes evident that symbioses encompass a lot of subtle interaction forms that are not normally seen as belonging in this category. An illustrative case is so-called *plant signaling*. Undamaged fava beans (*Vicia faba*), for instance, immediately started to attract aphid parasites (*Aphidius ervi*) after having been grown in a sterilized nutrient medium in which aphid-infected fava beans had previously grown. The damaged beans thus had managed to signal their predicament through the medium to the undamaged beans, which then immediately started to attract aphid *parasites*, although no aphids were, of course, available for parasites to find.

The difference between this kind of *semiotic mutualism*, involving a delicate balance of interactions between many species, and symbiosis proper is one of degree rather than one of kind, and biosemiotics takes semiotic mutualism to be not only widespread in nature but nearly ubiquitous. This implies that the relative *fitness* of

changed morphological or behavioral traits becomes dependent on the whole system of existing semiotic relations that the species finds itself a part of and, accordingly, the firm organism-versus-environment borderline will be dissolved, and a new integrative level intermediate between the species and the ecosystem would have to be considered – that is, the level of the *ecosemiotic interaction structure* (Hoffmeyer 2008). Clearly, this possibility becomes most interesting in cases where experience and learning enter the interaction pattern, as will often be the case in mammals and birds. Such learning might on occasion even subsume the evolutionary process, as is the case in human culture. Conversely, one might wonder if a relatively autonomous ecosemiotic interaction structure is precisely what is needed for learning to evolve in the first place. In this way, eventual increases in semiotic freedom, that is, the capacity of a system to derive useful information from complex signs, will be prone to feed back into the evolutionary process by strengthening the advantages of possessing semiotic freedom. It follows that the evolutionary dynamics would possess an inbuilt tendency to invent and establish species exhibiting more and more *semiotic freedom* in the sense that their behavior would be increasingly underdetermined by the constraints of natural lawfulness and increasingly dependent on the in situ interpretative capacity of individual organisms.

Biosemiotics and the Science-Religion Debate

Biosemiotics has strong implications for the science-religion question: (a) It rejects the dualistic conception of mind and matter as well as the derived distinction between materialism and idealism, (b) it introduces a notion of semiotic causality and thus of agency in organismic life, (c) it suggests a naturalistic account of the experiential world and thus locates the human being in all its dimension as a natural being, and (d) it introduces a changed conception of individuality and thus of life and death.

Rejection of Dualism

Pondering what kind of thing a sign is, we must find an answer to the question of what makes a thing to be *of* or *about* another. The classical answer to this question has been that it takes human intentionality to produce this effect. According to Brentano and Husserl, we can define mental phenomena as those phenomena which contain an object intentionally within themselves. For all we know, a rock will not itself take any interest in its own past, whereas a geologist or even a climber most likely in their minds would form some idea of the rock's now absent past and they would do so even while sitting at home and thinking about the rock. The rock does not possess intentionality but humans do. Up through the twentieth century, this understanding has legitimated the so-called glottocentric character of semiotics. From Saussure and onward, human speech was considered the paradigm case of semiosis.

But what about the apes? A biologist immediately has to ask such a question for since nothing in evolution comes for free, there must be some line of argument telling us why humans possess such an unlikely capacity as intentionality when the rest of nature patently is deprived of it.

According to biosemiotics all living systems are constitutively sign users, and as support for this view, most biosemioticians would commit themselves to a Peircean understanding of the sign. As we saw the Peircean sign is “pure relation” connecting three entities irrespective of their kind in an act of forming an interpretant.

The implication of this is that pure relations may have causal power in the world – signs make things happen – but to suggest such a thing implies a negation of the distinction between materialistic and idealistic ontology. It must immediately be remarked here that relations do not, of course, have causal power per se. The black cloud I saw a few minutes ago was clearly related to the heavy rain falling now, but the reason I brought an umbrella is not this relation itself but the fact that an interpretant was formed in my mind relating these two phenomena into a triadic sign relation. By far the most relations in this world have absolutely no effects

upon the world; thus, the relation between planet Jupiter and my thumbnail is not likely to ever be implicated in any material events in the universe. (The funny thing is that because I just wrote this true sentence, it is no longer true. In fact the relation between Jupiter and my thumbnail has now entered my intellectual world and thereby changed the pattern of ink in my printed manuscript and successively, I must expect, will it change the pattern of ink and paper a great many copies of the present book. To the extent my mention of the relation has provoked thoughts in my reader, it may even have caused further sorts of unpredictable results.) But when life first originated on the cooling Earth, some physicochemical regularities must already have become sufficiently stable for primitive life forms to use them as predictive tools, that is, as signs, telling them how to adjust their activities. Living systems are per definition anticipatory systems, and in the anticipatory process, simple dyadic relations, that is, regularities, must have been the basis for the formation of genuine triadic sign relations. I have suggested we call this phenomenon *semiotic causality*, that is, the bringing about of things under guidance of interpretation in a local context.

Semiotic Causality and Agency

To account for the evolutionary appearance of semiotic causality is probably the most challenging problem in the whole complex of questions treated under the umbrella of “origin of life.” Several approaches to this problem have recently been proposed drawing on new developments in studies of complexity and self-organization. The deep question at stake here, of course, is whether it is possible to give a naturalistic account for the teleological character of natural systems. As we have already seen, biosemiotics rejects the eliminativist attempts to explain away this problem by claiming that the telos of natural systems is only an “as if” telos that may ultimately be accounted for in terms of natural selection. The reader is referred to a recent consensus paper by Kalevi Kull, Terrence Deacon, Claus Emmeche, Jesper Hoffmeyer, and Frederik Stjernfelt for a deeper treatment of this question (Kull et al. [in press](#)).

Needless to say, semiotic causality is related to that most tabooed kind of causality normally called final causality. The concept final causality however has been contaminated with misunderstandings and also hijacked for a variety of purposes that were never implied by Aristotle himself when coining the term. Rather than entering this confusing discussion, I shall call attention to the obvious fact that semiotic causality depends on ordinary efficient causality for its operation. Sign relations do not themselves “move” the world; what they do is to organize the “moving power” under an intentionality inherent to the interpreting system. Thus, my taking the black cloud to be a sign fortunately organized my muscular power so as to fetch my umbrella and thus prevent me from getting wet.

Semiotic causation is the very core principle behind the *agency* of life. Nonhuman organisms do not ever try to survive (for the simple reason that they do not know that they shall die). But all of them do exhibit agency: They ceaselessly strive to find nourishment, find shelter, escape predators, and find mating partners or whatever is necessary for them to do in their life.

Humans Are Natural Beings

On this background we can now make the assertion that the sign relation, as exhibited by the very first life forms, was the germ form for what through billions of years of evolution gradually developed to become – among many other things – human mind. Thus, biosemiotics implies that the spiritual life of humans need not be a result of supranatural intervention but may instead be seen as a peculiar and highly elaborated instantiation of semiotic dynamics inherent to life as this has unfolded on Earth from its first beginnings.

To work out a theory of how to explain the natural basis for the function of human mind processes is of course a mighty challenge and one we do not expect can ever be solved in detail. What concerns us here is just to point out that contrary to classical nonsemiotic neurobiology, biosemiotics, that is, neurosemiotics, does have a tool set that makes it possible to attack the problem in a nonreductionistic way.

Biosemiotics on Life and Death

Seeing human life in a biosemiotic perspective has important consequences for the evaluation of the many new challenges to our ethical judgment posed by the technological development in general and biomedicine in particular. Perhaps most significantly biosemiotics dissolves the borders around individual life and suggests a much more nuanced conception of life's beginning and its end.

The semiotization of biological life implies a loosening of the narrow binding of life to certain privileged and distinct structures (such as the genome or the individual) in favor of a conception that instead identifies the phenomenon of life with unbroken semiosis, growth, and cell division. In prokaryotes (that make up by far the majority of all living creatures on Earth), life is indeed an unbroken chain of daughter cells following upon daughter cells in a continuous flow of cell growth and division. To ask when, exactly, any one of these given cells started its life is utterly abstract – since the cell, both as far as its substance (cytoplasm) is concerned and as concerns its form (both its membrane and its genome), is connected to all ancestral organisms in the same unbroken line. In multicellular organisms such as plants or animals, one may of course speak of an *individual's* life that starts with the establishment of a single cell (the zygote in organisms that sexually reproduce) that multiplies through a web of cellular divisions, leading to the formation of an adult individual. But as soon as one turns to consider the life cycles found in fungi, it readily becomes clear that the concept of the *individual* that seems suitable for the life cycles of animals and humans cannot be generalized to life processes per se. Many fungal species, for example, spend the major part of their life cycle carrying two autonomous nuclei (one male and one female) in each cell. Conception has been frozen in place, so to say, at the moment right before these two nuclei would normally fuse in plants or animals. The fusion of the two nuclei takes place only at the ultimate end of this phase of dikaryotic life (*karyon* = cell nucleus) whereby, finally, a proper diploid cell is formed. This “normal” diploid cell, however,

does not last for long but instead quickly divides itself again under the formation of haploid spores (sex cells with only one set of chromosomes). These haploid cells are then ready to fuse with haploid cells of the opposite sex whereby a new phase of *dikaryotic* life begins.

Thus, in these fungi, the diploid phase – that condition that we humans without further reflection take to be a proper *individual's* life – is reduced to only one short intermezzo in between two extended phases of tight common haploid life. Here the process of fertilization has been stretched, so to say, to occupy nearly the whole of the organism's life. Diploid life, such as we know it from ourselves, cannot therefore biologically be seen as being the privileged form of individual life. And one consequence of this is that *the starting point of an individual human life is not a biologically meaningful concept*. To the extent this concept has any meaning at all, it is a meaning that is derived elsewhere than from biology. For human life, just like all other forms of life, is, from the biological perspective, an unbroken chain of growth and cell divisions.

However, the fact that every human being nevertheless is very intimately connected to just one individual life therefore calls for an explanation that cannot be derived from the mere biological fact that human beings are living creatures. If we want to explain why human life is seen as so narrowly connected to our experience as individuals, we had better search for the explanation in the peculiarity of the human form of life and not as the result of life processes in general. And here the overarching distinguishing mark between the human form of life and all others is the extraordinary semiotic agility possessed by this big-brained animal.

From these deliberations follows a conclusion of deep significance for ethical discussions in the medical area: *The individuality of a human life cannot be justified by its uniqueness as a particular genetic combination, but must be justified by its uniqueness as a particular semiotic creature*. Semiotic uniqueness is different in kind from genomic uniqueness because it depends on a potential that bears an inherent *indeterminacy*

and *creativity* – a potential, furthermore, that we humans know much better how to evaluate and enjoy than is made possible through the severe determinacy of genomic specification. *Human* uniqueness, then, is not *molecular*, but *semiotic*. And from this it follows that the readily felt irreplaceability of a human being is rooted in its *semiotic individuation process*.

This conclusion leads us to the emotionally troublesome consequence that an objective answer cannot be given to the question of *when* a human life starts and stops being irreplaceable. Considered as a genome, it is irreplaceable from the moment of fertilization – and the ethics of irreplaceability within the viewpoint of genomic individuality logically leads to a rejection of any and all manipulation with embryos. But if instead we ask the question of when the semiotic individuation process of a fertilized egg cell is sufficiently far advanced that an abortion would be a violation of a human life, no clear answer presents itself.

The biosemiotic understanding in reality forces us into an evaluation of a more-or-less situation. Humanhood thus becomes a more-or-less property! And thus – as with most other essential questions of life – the question of whether a technical intervention destroys a *human* life depends on a process of reflexive pros and cons, and thus, each single instance of technical intervention must be evaluated through a concrete analysis. There simply is no *unitary procedure* – neither rational nor ethical – upon which such ethical judgments can otherwise be safely based.

Through this loosening of *individuality* from the genomic absolute, the inviolability of life becomes not theoretical and absolute, but specifically embodied and concrete. The stricture that you must not kill another human being does not then depend on a principle of human inviolability, but upon the fact that such an act will lead to the elimination of an invaluable semiotic richness – one that demands our deepest empathy. It is the existential ability to identify ourselves with other semiotically free systems that stands as the pivotal point of ethics within the biosemiotic perspective.

Black Holes

Russell Stannard
Department of Physics and Astronomy,
Open University, Milton Keynes, UK

A region of space having a gravitational field so intense that no matter or radiation can escape it. It is formed when a massive star runs out of fuel and can no longer hold itself up under its own gravity. It collapses with the emission of a supernova

explosion, leaving behind an exceedingly dense core that is believed to end up as a point, or singularity. It is surrounded by an event horizon which is a theoretical surface enclosing the region from which there can be no escape. Black holes are also thought to be formed at the centre of galaxies through the progressive capture of the stars in that region. Black holes are described in general relativity theory as regions where the curvature of space is particularly pronounced.

Blindsight

A Brief History of Blindsight

The term “blindsight” denotes a type of unconscious vision observed in neurological patients whose *primary visual cortex* (V1, striate cortex) was damaged or denervated. Such brain damage causes *homonymous visual field defects* in the half-field contralateral to the lesioned hemisphere. If the field defect is *absolute*, the patients are blind in the affected region and fail to report visual stimuli and objects that are confined to it. This is the “blind” in “blindsight.” The “sight” refers to the visual functions that can be demonstrated despite the loss of conscious vision the patients experience. “Blindsight” captures the dissociation between their visually guided responses and their perceptual report.

Before blindsight was described in human patients, experimental psychologists including Heinrich Klüver (1949) and Lawrence Weiskrantz (1986) had demonstrated that

monkeys whose primary visual cortex was surgically removed in one or both hemispheres could recover some responsivity to visual stimuli. The discrepancy between the loss of conscious sight that human patients reported to suffer from destruction of V1 and the visual responses demonstrated by monkeys despite similar destruction was interpreted as evidence for the monkeys’ lesser *corticalization*. Their residual visual functions appeared to indicate reduced functionality rather than blindness, implying that their sight was less dependent on visual cortex than that of man. This hypothesis lost appeal when patients, instead of only being asked whether they saw the visual stimuli presented in their cortically blind field, began to be tested with *forced choice methods*, like the monkeys. Asking a patient to point her eyes or hand to where she thought a briefly presented stimulus might have been, or to guess whether or not it had been moving, even if she did not see it, revealed that patients too responded much better than what could be expected from chance guessing (Pöppel et al. 1973). Blindsight, human blindsight, owes its discovery to the combination of testing procedures that ask for perceptual report with those suited to uncover implicit or covert stimulus processing.

The early reports of human blindsight that were published in the 1970s met with skepticism. Neuroendocrine or reflexive responses elicited from the blind field would have been easy to accept as they are under little if any voluntary control and indeed visual reflexes can be elicited with blind-field stimuli. But the notion that man could respond voluntarily and non-reflexively to information he/she could not consciously see or know seemed preposterous. Methodological points of critique – like detection of stray light, eye movements bringing the stimuli from the blind into the sighted field, decision criteria stricter in the affected than the normal field – were raised to suggest the results were artifactual (Campion et al. 1983). Blindsight research painstakingly addressed them, and its methods clearly profited in the process. The phenomenon however persisted, and, together with covert memory in amnesic patients, became a prime example of implicit processes in neurological patients.

Meanwhile, research further detailed the discriminations that could be demonstrated in the absence of primary visual cortex in man and monkey. Stimulus localization, detection of light, discrimination of stimulus intensity, orientation, motion direction, amount of contour, wavelength, and shape were examined, revealing closely corresponding residual functions in human and simian subjects. The “hard” question of whether monkeys have blindsight like human patients was addressed in 1995, when two groups published results of experiments designed to learn whether *hemianopic* monkeys “saw” the blind-field targets to which they responded. In brief, both groups used target localization tasks and confirmed that their monkeys could quite accurately touch or look toward stimulus positions in the blind field, but added different twists to learn about stimulus awareness. Arguing that unlike patients, monkeys were not given an option to indicate that they did not see a stimulus, the first group added a *detection task* to the localization that their monkeys had already mastered. As before, the position where brief visual stimuli, brighter in the blind field to compensate its loss of sensitivity, appeared was to be touched to gain a reward. But on new no-stimulus (“blank”) trials, monkeys were to touch a special outlined region on the screen. Would they touch it only on blank trials, indicating “no” when no physical target was present? Or would they also touch it on blind-field target trials, indicating that they did not see the physically present target? The results were clear. Hemianopic monkeys treated blind-field stimuli as blanks when given the option to signal “no stimulus” (Covey and Stoerig 1995). The second group argued that their monkeys would not direct their eyes to a blind-field stimulus unless they either saw it or, if blind, were cued as to its presence (not position). Omitting the dimming of the fixation point that had served as a cue indeed caused a massive drop in the blind-field performance of adult-lesion animals (Moore et al. 1995). This evidence of monkey blindsight completed the loop of the trajectory of blindsight research: Beginning with the cortical blindness patients reported, it moved to the visual functions of

monkeys devoid of (striate) visual cortex and on to similar functions in hemianopic humans, and finally arrived at blindsight in man and monkey (Stoerig and Covey 1997).

Blindsight is not a discipline. It is a phenomenon that has attracted experimental psychologists, neuroscientists, neurologists, cognitive scientists, and philosophers, who study the phenomenon and pursue the in-roads to a better understanding of consciousness in general and visual awareness in particular that it promises. Questions blindsight may help to answer include: What is its neuronal basis, and how does it differ from that of conscious sight? What species have it, and do they then have conscious sight too? What is it good for, what are its limits? What are the functions and advantages of conscious versus blindsight? Certainly blindsight is not a religion either, but some of the issues it raises do impact on both ethical considerations and religious beliefs. I will address the questions posed above in turn.

The neuronal basis of blindsight. Destruction of V1 causes degeneration of the dorsal lateral geniculate nucleus (dLGN) of the thalamus. Transneuronally, this process will affect the retinal ganglion cells that normally provide the retinal input to the dLGN which in turn transmits it on to V1; the retinal ganglion cell layer will shrink where its cells lost their target neurons. Factors like age at lesion, primate species, retinal eccentricity, and ganglion cell type impact extent and speed of transneuronal degeneration. Blindsight must be mediated by the surviving ganglion that project to midbrain as well as thalamic and hypothalamic structures. These transmit the retinal information to further nuclei that, directly or indirectly, pass it on to higher visual cortical areas. The participation of visual cortical areas has been demonstrated physiologically in monkey and, with functional neuroimaging, in man; it indicates that blindsight is not blind because it relies solely on subcortical processing. Moreover, the engagement of a host of retino-recipient structures suggests that different blindsight functions rely on pathways that also mediate this type of function in the healthy brain. Indeed, extensive series of experiments conducted to elucidate how different residual

functions displayed by anopic monkeys were affected by additional cortical or subcortical lesions revealed how different functions ranging from brightness discrimination to manual localization and shape discrimination depend on pretectal, collicular, and higher visual cortical regions (Pasik and Pasik 1982). The missing ingredient that is responsible for the blindness is still being sought in precise temporal neural interaction, in integration of visual and unspecific thalamic, respectively, frontoparietal processes, or in blindsight's dependency on occipitoparietal more than occipitotemporal processing.

Blindsight in different species: Investigations of blindsight have predominantly been performed on man, other primates, and cat. Whether blindsight is always and completely blind however is still debated in the first two and has not been addressed in cats or the other, often rodent species that have been studied. As blindsight implies voluntary visual responses when conscious sight has been lost due to V1 damage, experimental designs need to implicitly or explicitly capture a feature that distinguishes, as convincingly as possible, between these two types of sight.

Functions of blind- and conscious sight: Knowing what one can do based on conscious but not blindsight, or vice versa, would help greatly to zero in on such features. Experimental evidence comes from a recent study of human blindsight that showed that blind-seen distractors seem more difficult to suppress attentionally than consciously seen ones (Stoerig 2011). More comes from Humphrey's famous bilaterally de-striated monkey Helen who exemplarily demonstrated both how stunningly her visual abilities improved when she went from being tested in her cage to eventually taking walks in woods and meadows, and how her discriminability suffered when stimuli were matched for salience or when she was frightened (Humphrey 1974).

These three questions are interdependent; answers to one will help sharpen and refocus approaches to the others. But there are clearly more such questions not explicitly posed here. Those addressing the possibility of improving blindsight, circumstances under which conscious sight will recover, and means to further this

recovery are among them, and contained in the definition of blindsight as residual visual functions that remain or recover in fields of absolute *cortical blindness*. There is potential in blindsight to impact rehabilitation as well as enquiries along the borderline between conscious and unconscious functions.

Bodhisattva Ideal

Bhikkhu Anālayo
Center for Buddhist Studies, University of
Hamburg, Hamburg, Germany

[Bodhisatta \[ideal\] \(Pāli\)](#)

Description

According to Buddhist tradition, a bodhisattva is one who has embarked on the path to becoming a Buddha in the future. Behind the idea of following such a path stands a distinction in Buddhist thought between different types of fully awakened beings. One such type is the arhat (Pāli arahant), who has reached the consummation of the early Buddhist soteriological path to liberation in dependence on having received the teachings of a Buddha. A Buddha, on the other hand, is a fully awakened being who has accomplished the goal of complete liberation without the guidance of another (further distinguished into the Pratyekabuddha, who does not teach others, and a Buddha, who delivers teachings).

Buddhist tradition holds that, unlike arhats in the narrow sense of the word, a Buddha manifests only on rare occasions in the history of the universe. In the early texts, a Buddha is depicted as unique, in the sense of being without equal, and is held invariably to be a male from a high class. In contrast, any number of arhats can coexist with each other, and an arhat can be of any gender or social class.

A bodhisattva is thus one who, instead of aspiring to become an arhat, wishes to reach the unique position of becoming a Buddha in the future – that is, at a time when the teachings given by a previous Buddha have disappeared – thus becoming one who on his own discovers the truth anew and then teaches it to others.

The term bodhisattva, literally an “awakening being,” according to modern scholarship, appears to be a wrong Sanskritization of an original term that would have been more correctly rendered into Sanskrit as *bodhisakta*. On this understanding, the term would refer to someone who has wholly “attached [himself or herself] to awakening,” in the sense of being fully intent on reaching this goal.

The concept of a bodhisattva is already found in the texts of early Buddhism, where it stands predominantly for the historical Buddha Gautama during the period in his last life that preceded his attainment of awakening. Already

within these early texts, some developments can be discerned which would eventually have led to the evolution of the bodhisattva concept into becoming an ideal to be emulated by others (Anālayo 2010).

The early stages of the bodhisattva ideal appear to have evolved within a context related to ascetic conduct and a forest lifestyle. The aim of compassionate activity for the sake of others seems to be a slightly later element, in spite of its eventual prominence as the defining characteristic of a bodhisattva, who is willing to sacrifice even himself in order to be able to lead others to awakening.

As a full-fledged ideal, the bodhisattva path differs from the path to awakening undertaken by one who aspires to the goal of arhatship. A disciple of a Buddha, a *śrāvaka*, who aims at becoming an arhat, needs above all to develop the noble eightfold path (► [Truths, Four Noble](#)) and the seven factors of awakening – mindfulness, investigation of phenomena, energy, joy, tranquility, concentration, and equanimity.

For the bodhisattva who aspires to Buddhahood – thus being one who has aroused the *bodhicitta*, the mind (that aspires) to the awakening (of a Buddha) – another set of qualities are of central importance. These are the perfections (► [Pāramitā](#)), standard listings of which comprise either six or ten qualities that need to be perfected. Common ground among the two listings can be found in the qualities of generosity, morality, patience, energy, and wisdom. While the sixfold listing adds the meditative development of absorption to the aforementioned five qualities, the tenfold listing adds instead renunciation, truthfulness, resolution, loving kindness, and equanimity.

Besides emphasizing different sets of qualities as the medium of progress, another difference concerns the stages of progress. The aspirant to arhatship proceeds through four levels of awakening: stream entry, once return, nonreturn, and arhatship (► [Awakening](#)). These four stages of awakening can in principle be attained within a single lifetime.

The bodhisattva, according to a listing in a well-known text by the name of

Daśabhūmika-sūtra, instead proceeds through what are ten distinct stages (Rahder 1926). As regards the stages of a bodhisattva's progress, however, considerable variety in listings and interpretations can be found in different textual strands and at times even within the same scripture.

The path to becoming a Buddha is also held to require dedicated practice over a series of lifetimes. This mirrors the belief that the historical Buddha had been preparing himself over innumerable past lives – some of which are described in the so-called *jātaka* collections, tales of past lives of the Buddha – so as to acquire all the qualities required in order to fulfill the role of a Buddha. Given the need to maintain continuity of practice over many lives, a bodhisattva at some point makes a firm resolve to embark on the path to Buddhahood, a resolve that is traditionally referred to as the bodhisattva vow. An important element of the aspiration to reach the awakening of a Buddha is the ritualized undertaking of bodhisattva precepts. In due course of time, the bodhisattva then receives a prediction of his future successful achievement of Buddhahood from another Buddha.

The aspiration to become a Buddha in the future is a common feature of the various Buddhist traditions and, somewhat against common belief, not the sole property of the Mahāyāna traditions. For many centuries, the bodhisattva ideal has had and still has its followers among eminent members of the Theravāda tradition (⇒ Buddhist schools and traditions), lay and monastic alike (Ratnayaka 1985; Samuels 1997; Harvey 2007). What distinguishes the Mahāyāna traditions is an emphasis on the bodhisattva path as the chief goal of one's aspiration, whereas in the Theravāda tradition the path to Buddhahood is considered only an alternative – a considerably more demanding alternative – to the path to arhatship.

The term Hīnayāna – the “lesser vehicle” usually contrasted to the Mahāyāna – does in fact not refer to the Theravāda tradition or to any other living Buddhist tradition but rather derives its meaning from the context of certain polemical strands found in Mahāyāna scriptures. The conceptual backdrop to these strands is

the notion that the path of the bodhisattva is the supreme form of practice which leads to a type of awakening that is superior to the full awakening attained by the disciple of a Buddha (► [Awakening](#)).

In sum, the bodhisattva ideal, although not found in the earliest strata of Buddhist texts, has played a central role throughout the history of Buddhism and is still a common property of the different extant Buddhist traditions, motivated by the wish to combine the freedom of awakening with the compassionate aspiration to alleviate the suffering of others.

Body

Jennifer L. Baldwin
Lutheran School of Theology at Chicago,
Chicago, IL, USA

Description

In the opening word of his text, “Theologies of the Body: Humanist and Christian,” Benedict Ashley writes, “I exist and live as a body in a world of bodies” (p. 3). On one hand, Ashley’s statement seems as intuitively obvious as the sky is blue; however, on the other hand, like the color of the sky which can contain the colors of the spectrum, Ashley’s confession that he “exist[s] and live[s] as a body in a world of bodies” may require additional thought. The question of the relationship between the subjective “me” and the body has been fodder for philosophical, scientific, and theological reflection for two millennia. The issues of the soul and self are addressed in other entries. But what about the body?

The body is most generally defined as the physical structure and material substance of an entity. This definition is a helpful entry into the great variety of ways in which “body” is utilized in science and religion discourse. “Body” can be employed in literal, symbolic, and/or metaphorical uses. It can refer to the human body, planetary bodies, a “body” of literature within a field, or the “body” of Christ, just to name a few. In the first two examples, the word “body” refers to the physical structure or material substance of the entity; however, in the latter two examples, “body” takes on a more symbolic or metaphorical sense. Within the sciences, natural and social, bodies are often sites of inquiry and investigation. Bodies are also tools for engaging in scientific research. We use our senses to interact with and gain knowledge

about all other bodies we encounter during our lifetime. We also employ our bodies to communicate our experiences and insights to others. We are highly embodied creatures.

Western philosophical and theological views of the body are highly reflective of the legacy of mind-body dualism. Dualism gained popularity and notoriety due to the work of René Descartes (1596–1650); however, it has historical antecedents in the thought of Plato (428–347 BCE) and, in a modified form, Augustine (354–430). Dualism effectively placed a wedge between the body and the mind, soul, or self to the extent that “mind,” “soul,” and “spirit” are often considered antonyms of “body.” The mind, soul, and spirit are more subjective phenomena and have captured the attention of philosophy and theology, while the body as an objective entity garnered the attention of science. Consequently, the body has rarely been attended to with the same precision, attention, and favor as the mind, soul, or self by Western philosophy and theology. Fortunately, the body is gaining more attention within philosophy and theology as a locus of research. Philosophy and theology’s turn toward the body has been most pronounced among feminist and environmental scholars.

The world’s religious traditions share ambivalence toward the body. In the *Bhagavad Gita* of Hinduism, the body is likened to a garment. “Worn-out garments are shed by the body. Worn-out bodies are shed by the dweller within the body. New bodies are donned by the dweller, like garments” (*Bhagavad Gita* II.22). In Buddhist thought, the body is considered the site of pleasure and pain that impede one’s path to enlightenment; however, enlightenment is within the human realm. Therefore, the body can be trained via meditation and discipline to approach a state of enlightenment. In the Abrahamic religions – Judaism, Christianity, and Islam – bodies are a part of the created order that is declared “good.” Human bodies are also considered to be in a “fallen” and “sinful” state. Consequently, the “goodness” of bodies as we encounter them is in question.

Given the ambivalence toward the body present within each of the major world religions and

the scientific understanding of the body as a site of inquiry and investigation as well as an instrument in investigation, how is “body” articulated and utilized in science and religion? It is perhaps not surprising to note that “body” manifests in a variety of ways, depending on the particular crossroad of disciplines and religious traditions. Bodies can be treated as inherently valuable and good, divided and analyzed according to their constitutive parts, or viewed as soon-to-be unnecessary material limiting the individual’s full potential. Bodies can be organic and living or inorganic. Bodies can be theological or philosophical concepts. All of the following types of bodies are discussed in science and religion literature. There are three main ways in which science and religion have addressed body: from within the mind-body discussion, by focusing on a specific part of the body (specifically the brain), and in conversation with technology. Each of these approaches primarily, though not exclusively, engages the human body.

The mind-body problem and question of mental causation has been a perennial concern for scholars from a variety of philosophical, scientific, and theological disciplines and traditions. Consequently, the question of the relationship between the mind and body is ripe for interdisciplinary attention. Concepts of the soul, immortality of the soul, reincarnation, and resurrection prompt religious and theological reflections as well as involvement in the philosophical question. Nancey Murphy, a theologian/philosopher, and Warren Brown, a psychologist, have spent considerable time on the issue and promoted the idea of a “nonreductive physicalism.” Philip Clayton provides a different approach by drawing on theories drawn from quantum physics and cosmology to the concept of emergence in order to negotiate the space between reductive physicalism and dualism. Although the idea of mind-body dualism is historically well established, it remains a fertile ground for thinking about the body in science and religion.

The second most prevalent way in which science and religion address the body is by focusing on one particular part of the body.

Interdisciplinary research has often focused on the brain as a site of inquiry. The brain is of particular interest due to its unique role in cognitive capacity and identity formation. For many scholars, the brain is the place in which the mind and the body intersect. Consequently, in recent decades, there has been an explosion of interdisciplinary research utilizing the cognitive sciences, including neuroscience, neuroimaging, and psychology, to investigate religious phenomena. For example, Andrew Newberg and Eugene D'Aquili employ neuroscience to argue that religiosity is rooted in the biology of the brain, while James Ashbrook and Carol Rausch Albright show that neuroscience and religious belief can challenge and enrich each other. The focus on the body employed by each of these interdisciplinary approaches and those like them is a focus on the brain as a part, arguably a unique part, of the body.

Finally, scholarship in science and religion has investigated the ways in which bodies interact with technology and the impact of technology on the body. This area includes the intersection of theological anthropology with biotechnology, artificial intelligence, and posthumanism. In all three of these areas, philosophical and theological questions center on the body and how the body is altered by the use and implementation of technology. Philip Hefner locates humanity's spiritual journey in technology. "Everything we think about religion, everything we think is *spiritual* is rearranged by technology" (*Technology and Human Becoming*, p. 12). Referring to Teilhard de Chardin, Hefner says, "For him the question can never be first of all 'what are we *doing* with our technology?' but it must be 'what are we *becoming* with our technology?'" For those working with artificial intelligence and robotics, the question focuses on "what makes a human being human?" How one answers the question of the quintessential attribute of humanity influences how one relates to robotics and artificial intelligence as well as how one opts to proceed in the posthumanist task of isolating and preserving the human mind while discarding the body.

At this point, we return to the question "what about the body?" "Body" in science and religion discourse can take on a plurality of meanings and uses depending on the intellectual context. Human beings do, in fact, "exist and live as a body in a world of bodies." The ways in which we consider what it means to be a body in the midst of other bodies, human and nonhuman, are vital areas of inquiry for science and religion.

Brain Death

Rüdiger J. Seitz

Department of Neurology, Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany

Brain death describes a medical condition in which all brain functions have ceased while the other organs of the body continue to function normally. On neurological examination the patients are in coma and all reflexes mediated by their brain stem are lost. Ultimately, the patients do not breathe spontaneously and remain unresponsive (apnoeic) upon an oxygenated CO₂-challenge. The electroencephalogram reveals a complete absence of electric brain activity in all parts of the brain. On autopsy the entire brain is necrotic. This condition occurs in patients with severe brain damage (e.g., brain trauma, stroke, cerebral hypoxia due to cardiac arrest) who had undergone vital resuscitation and are treated with artificial ventilation on an intensive care unit. In the Western countries legal guidelines were developed how to identify this condition and to prove its irreversibility both in adults and children. These guidelines include the formal documentation of the presence of the diagnostic criteria of brain death by two independent physicians with an expertise of intensive care medicine at two predefined time points. These standards are object of continuous evidence-based evolution (Wijdicks et al. 2010). The fulfilment of their requirements is the prerequisite for organ donation in transplantation medicine.

[Artificial minds](#); [Artilects \(artificial intellects\)](#); [Brain building](#); [Computer science](#)

Artificial Brains (ABs), as its name suggests, is a branch of artificial intelligence (AI) which attempts to build artificial brains, i.e., engineered brains. The most common approach is to use modern electronics and often robotics to give the artificial brains bodies to control. Typically, an artificial brain is hidden in the software of a computer, so one can only judge the quality of the artificial brain's control by the quality of the behaviors of the robot as seen by human observers.

Modern and near future (i.e., within 10 years) electronics is providing a gargantuan number of transistors on a chip. This number is doubling every year or two, a phenomenon called “Moore’s Law,” after Gordon Moore, one of the founders of the microchip company “Intel,” noticed the trend and wrote about it in 1965. Moore’s Law has been valid for over 40 years

and is thought that it will remain valid for at least another decade (by which time, transistors will be the size of atoms.)

Today's chips have over a billion transistors. By the year 2020 approximately, computer systems will contain trillions of trillions of components, because they will be of molecular scale (i.e., using "nanotechnology," or "molecular scale engineering"). This vast electronic capacity that is about to explode upon us is making the construction of artificial brains both realistic and practical.

At the same time, modern neuroscience is furnishing detailed knowledge of the micro-circuitry of the rat brain, providing data on how each neuron (brain cell) connects to roughly 10,000 other neurons in a single "cortical column" that consists of about 10,000 neurons. The rat brain has about 1,000 such columns. The human brain has about a million. The leader in this work is Henry Markram at EPFL in Switzerland [Markram]. He calculates, using Moore's Law, that within a decade, he will be able to obtain similarly detailed knowledge of the whole rat brain. It will thus be possible to *perform neuroscience experiments in a computer*, a revolutionary concept that is sometimes labeled "e-NS" (i.e., electronic neuroscience). Thus, Moore's Law and e-NS combined will have revolutionary consequences for humanity as detailed knowledge as to how the human brain works is incorporated into artificial brains, speeded up a million times, and with virtually unlimited memory and number of sensors.

As a concrete example of an artificial brain, the author uses modern electronics to evolve neural network modules, each with its own small task (de Garis 2002). Thousands of these evolved modules are downloaded into a supercomputer (or even an ordinary PC) and connected up according to the architectures of human "BAs" (brain architects) to build artificial brains that control hundreds of behaviors of two legged, two armed robots that can see, walk, grab, talk, listen, understand (to a moderate degree), remember, reason, etc.

The advent of such artifacts, even if only mildly intelligent, would probably become one

of the world's biggest industries, when useful home robots could be controlled by an artificial brain. As a result of this work, this field might play a major technological, economic, political, and even religious role later in the century.

Self-Identification

Science

There is little doubt that the field of Artificial Brains is a science. Brain builders are constantly testing their hypotheses as to how to build intelligence into a machine, in the form of artificial brains. These hypotheses are then embodied by implementing them in (usually) computer systems and robots, to see whether the implemented reality conforms to the original hypotheses. Building such an artificial brain would be a definitive test of humanity's understanding of how the human brain works.

Religion

The main idea of de Garis (2005) is that this century's global politics will be dominated by the question whether humanity should build "artilects" (i.e., artificial intellects, i.e., massively intelligent machines) or not. The author sees humanity dividing into two main ideological camps, labeled "Cosmists" (who are in favor of building artilects) and "Terrans" (who are opposed).

The Cosmists would be in favor of building artilects, because building artilects would be like "building gods." Artilects would be trillions of times more intelligent than human beings, they would be immortal, could change their form in milliseconds, have unlimited memory, go anywhere, do anything, understand hugely more. They would be gods.

Characteristics

Understanding the human brain is one of the greatest scientific challenges of the twenty-first century. The field of artificial brains is distinctive for three specific reasons of being (a) politically

consequential, (b) scientifically fascinating, and (c) economically important.

Many of the growing number of artificial brain researchers feel that they are in a field that is of great consequence, which is historically similar in prestige level to that enjoyed by the nuclear physicists in the 1940s and 1950s. Brain builders believe that in the longer term, the consequences of their work will end up dominating this century's global politics. This is not something to be sneezed at. It is terribly important.

The field is also fascinating. Two of science's greatest mysteries are the nature of intelligence, and the nature of consciousness. Artificial brain researchers are usually fascinated by such questions and feel they are probably in the field that one day will give definitive answers to such questions.

The field will have huge economic consequences. This author has asked many people how much money they would be prepared to spend on a genuinely useful and intelligent *home* robot. The general answer tends to be "less than for a house, more than for a car." Since billions of people would want to buy a useful intelligent home robot, we are talking about one of the world's biggest industries, worth trillions of euros a year.

Relevance to Science and Religion

The majority of artificial brain researchers are not traditionally religious. They view traditional religions as superstitions unworthy of their respect. Modern scientific knowledge has effectively debased traditional religions and made ideas such as a "prayer" and "life after death," "miracles," "angels," "resurrections," "virgin births" seem ignorant and stupid. On the other hand, researchers in this field are not averse to religion, provided that it is interpreted in terms of modern scientific knowledge and critical thinking. For example, many of the author's colleagues are open to "deism" (i.e., the belief in a creator of the universe (multiverse)), but sneer at theism (i.e., deism, plus belief that the creator takes a loving personal interest in the welfare of individual human beings).

The theist hypothesis is easily refuted by the brute fact that the twentieth century was the bloodiest in history, with some 200–300 million people being killed for political reasons, e.g., wars, holocausts, and purges. Presumably many millions of these people believed in a loving god who obviously did not love them.

The deist hypothesis however is far more substantial, on at least two counts. One is the "anthropic principle" which states that the values of the constants in the laws of physics are so fantastically improbably finely tuned (in one (cosmological) case, to one part in 10 to power 60) to allow the existence of matter and life, that the strong suspicion is that the universe was "engineered," implying a designer, i.e., a "deity". It is possible, however, that future theoretical physics may discover symmetry principles so severe in their constraints that only one possible universe and laws of physics is possible and our universe is it. The jury is still out on this question, but any scientifically curious person ought to be open to the idea that the universe is "rigged," "engineered," "designed".

The second count is more directly derived from artificial brains. The idea that an artefact could become trillions of times superior to humans in intellectual ability makes one wonder what they would do to pass their (immortal) time. Considering that human beings (e.g., Prof Guth at MIT) have already created physical theories on how to build baby universes, what could an artefact do? With its vastly superior intellectual abilities and knowledge of how the universe works, perhaps, it would be capable of actually *building* universes with all their constituents, including living beings similar to ourselves. By definition, such an artefact would be a "god," i.e., a creator. Admittedly, it would not be as "powerful" or omnipotent a "god" as the creator of the preexisting universe that the artefact was created in (either by inferior artefacts or human beings). The artefact creator of the new universe would take as a given, the circumstances in which it found itself at its birth. What then created those circumstances, given that they obey the anthropic principle?

So, if the artefacts made by human beings eventually become capable of building universes,

then it is plausible that our universe is the product of some earlier artefact in some earlier universe. Hence, and this is a major point that the field of artificial brains can contribute to the field of “science and religion,” *the prospect that humanity’s artefacts may become godlike, capable of building new universes, makes brain builders much more open to deism*, i.e., they lose their “a-deism” that traditionally was so common to most scientists. There are good solid scientific reasons to keep an open mind on the topic of deism.

Sources of Authority

The research field of Artificial Brains is as authoritative as any other substantial science. It is however very new, so there has not yet been enough time for the field to establish its own scientific journals and conferences. At the time of writing, research papers on artificial brains are scattered over various specialties (e.g., robotics, AI, electronics, cognitive science, etc., e.g., [Markram], [Artificial Development]).

Ethical Principles

The answer to this question depends on the time frame one is talking about. In the coming few decades, it is likely that the rise of the intelligent home robot will be considered a wonderful thing by humanity, as a liberating force, freeing human beings from the “3Ds,” i.e., those jobs that are “dull, dirty, dangerous.” Everyone will want one; thus, there will not be much in the way to obstruct progress in building artificial brains in the early twenty-first century. Ethical constraints against such progress will be light.

However, longer term is a very different matter. Already, thousands of scientists and engineers have formed themselves into internet interest groups, e.g., [Transhumanists], [Extropians], [Singularity Institute], to debate the longer-term consequences for humanity, if we decide to build artefacts. In 2006, major TV documentaries appeared devoted to the issue of

species dominance (i.e., whether humanity should build artefacts or not), [BBC], [ABC], [Technocalyps]. In 2011, a movie appeared in the USA discussing the issue [Transcendent Man].

The major ethical issue is that of “species dominance.” Should humanity build artefacts or not? As described earlier, the Terrans would be bitterly opposed to the creation of artefacts and, in the limit, would go to war to stop the Cosmists (and the Cyborgs, i.e., people who add artefactual components to their brains to become artefacts themselves). The fundamental ethical principle upheld by the Terrans is that of “survival of the human species.” To Terrans, this principle is absolutely nonnegotiable.

The Cosmists, on the other hand, would be driven by a sense of awe at the grandeur of what artefacts could become, vastly outpacing the pathetic little human lives we live, snuffed out in a mere 80 years in a universe that is billions of years old, living on a tiny planet of one star of a trillion trillion in our universe. The fundamental ethical principle driving the Cosmists will be the powerful impulse to build gods.

The Cosmists will anticipate the hatred and fear of the Terrans and will be prepared for the Terran “first strike” (which the Terrans must do, if they are not to be utterly outclassed over time by the rise of the artefacts and the cyborgs-cybernetic organisms, i.e., part machine, part human).

Hence the ethical dispute over whether humanity should build artefacts or not, later this century, may result in the deaths of billions of people. This author considers this scenario the most probable and, unfortunately, the most horrible.

Key Values

During the first decades of the twenty-first century, the values of the brain builders have been to build artificial brains as intelligent and as useful as they can be. Since the early artificial brains will not be intelligent enough to be a threat to humanity’s “species dominance,” there will be

plenty of incentive to increase the artificial intelligence level and usefulness of the home robots, controlled by artificial brains. As the decades pass however, the values of the Cosmists and the Terrans would diverge, and diverge dangerously, leading to the ethical dilemma mentioned above.

Conceptualization

Nature/World

The majority of brain builders are materialists, metaphysically speaking. Like most neuroscientists, they take a functionalist attitude to brain building. They accept the idea that artificial intelligence can be put into a machine provided that the machine obeys the needed “principles of intelligence theory,” which unfortunately today are only vaguely elaborated.

Human Being

Most brain builders feel that human beings are molecular machines, subject to the same laws of physics and chemistry as anything else.

Life and Death

To brain builders, life is an extremely complex molecular system that metabolizes, reproduces, mutates, and evolves. How life started is still unexplained. Did life come from outer space, or did it start spontaneously on the earth as soon as geological conditions were appropriate?

Death is not universal. Bacteria and cells in general are immortal if constantly fed. Reproductive cells are immortal because there are elaborate and energetically expensive molecular repair mechanisms that fix deleterious mutations in germ line (i.e., reproductive) cells. Once sex was invented and body (or somatic) cells separated from reproductive cells, organisms did not survive long enough (due to accidental death, e.g., starving to death, being eaten, burned to death, disease, injury, etc) to make constant upkeep of the somatic cells worthwhile.

Since both life and death are molecular mechanisms, with genetic programs, it is

probable that humanity will discover scientifically the mechanisms that cause death in humans and learn to counter them by reprogramming the DNA.

Reality

Brain builders are not on the whole physicists, so their conception of reality is probably not very different from the “man in the street’s,” i.e., the human eye and brain “sees” what is “out there” (what the philosophers call “naive realism”). To the minority of brain builders who are (mathematical) physicists, the concept of reality is far more subtle. The interpretation of quantum mechanics is riddled with philosophical and conceptual puzzles, on the nature of reality, the nature of measurement, of superposition, of entanglement, and so forth.

Knowledge

Artificial brains will need to store knowledge and use it. AI has long struggled with the problem of knowledge representation. How does the brain store knowledge? How does the brain decide what incoming stimuli are worthy of storage? There are many questions both philosophical and very practical regarding the nature and use of knowledge in artificial brains.

Truth

Philosophically speaking, the brain builders’ concept of truth as applied to an artificial brain controlled robot is how well the robot “survives” in its world. If the ideas and models in the artificial brain allow the robot to manipulate its world successfully, then those ideas are ‘true’ in some pragmatic, Darwinian sense.

Perception

Perception is a critical concept to brain builders. In the author’s artificial brain, a substantial proportion of the evolved neural net modules that make up the brain are perception modules. Each one recognizes a particular pattern or feature, e.g., something red, a straight line moving left, a shoe, a particular person’s face, etc. Choosing what is important for an artificial

brain to perceive is an important set of design or architectural decisions for that brain.

Time

To a philosopher, the nature of time is as deeply mysterious as the nature of consciousness is to a brain builder. To a brain builder, the nature of time is much more pragmatic. The time concept is used to determine the sequence of events, the concurrency of two events (so essential for Hebbian learning and synaptic reinforcement when two connected neurons fire simultaneously due to the two hitherto separated events). Previous events, if considered important by the artificial brain, are stored for future use. The concept of time for an artificial brain is as basic as it is for human beings.

Consciousness

One of the deepest mysteries in the whole of science, and especially neuroscience and artificial brains, is the nature of consciousness. The philosophers talk about the “hard problem,” i.e., how will third party objective (external) discoveries about the behavior of the human brain *ever* be able to explain a person’s subjective (internal) feeling of being conscious of something (qualia)? It is indeed a deeply puzzling problem. Whatever consciousness is, it gets built. Embryos grow into human babies that are conscious and intelligent.

Rationality/Reason

Artificial brains will obviously need to reason if they are to be useful. A machine that cannot reason from its past memories will not be very intelligent. Hence, the nature of logic and types of logical reasoning are important topics for study when building artificial brains.

Mystery

There are many mysteries remaining in the field of Artificial Brains. Here are some – (a) What is intelligence? (b) How is intelligence built? (c) What is consciousness? (d) How are memories stored in the brain? (e) Can humans with human intelligence build artefacts with superior intelligence? (f) How does the brain make a decision? (g) Will it ever be possible for one

human brain to have the same conscious experiences as another person? (h) Is the red person A sees, the same red as person B sees? (i) How does the brain learn? (j) How can answers to the above questions be put into an artificial brain? (k) Will human level artificial intelligence ever be achievable without a deep knowledge of how the human brain works?

Relevant Themes

As mentioned above, *the prospect that humanity’s artefacts may become godlike, capable of building new universes, makes brain builders much more open to deism.* Traditionally, most scientists were atheists (and still are in the strict sense, i.e., when distinguishing between atheism and a-deism). Acceptance of the possibility of a creator, a “deity” is much more plausible now, less “anti scientific.” In fact, it is science itself that has made formerly a-deistic researchers more open to the possibility that our universe has been built by a vastly superior being, commonly known as “god.” The “anthropic principle” coming from physicists only confirms the reasonableness of this openness.

In short, deism (as distinct from theism, which most scientists still dismiss with contempt) is making a comeback. Deism is consistent with (but not conclusive from) the current scientific evidence. One should be open to the possibility that a “deity” made our universe.

Broaden-and-Build

Sarah A. Schnitker¹ and Robert A. Emmons²

¹School of Psychology, Fuller Theological Seminary, Pasadena, CA, USA

²Psychology Department, University of California, Davis, Davis, CA, USA

A theory of positive emotion function developed by Barbara Fredrickson, the broaden-and-build theory maintains that positive emotions are evolutionarily evolved adaptations that enhance survival by expanding the repertoire of behavioral options for organisms. The theory posits that the expanded cognitive flexibility evident during

positive emotional states leads to the accrual of physical, social, intellectual, and psychological resources across time.

Buddha (Historical)

Vishvapani Blomfield

Independent writer and researcher, Cardiff, UK

Related Terms

[Buddha](#); [Gautama](#) [Buddha](#); [Shakyamuni](#); [Siddhartha Gautama](#)

Description

“Buddha” is a title meaning “the one who has awakened,” and in the Pali and Sanskrit texts that comprise the early Buddhist scriptures, “the Buddha” is a historical individual called Gautama. In later Buddhism, this individual is blended with a legendary figure, and eventually, he becomes an eternal, archetypal Buddha figure called Shakyamuni. The early scriptures are our only source of information about the historical Gautama, but they cannot be viewed as wholly reliable: The contents were reportedly memorized in the Buddha’s lifetime, then recited communally, and finally committed to writing in the first century BCE. Some historians argue that we therefore cannot know if the Buddha existed at all as an historical individual (Penner 2009); but most read the texts critically to distinguish the historical Gautama from the figure celebrated by Buddhist legend and piety.

These texts survive in two main collections. Those in the Pali language, often known as “the Pali Canon,” form the main corpus of Theravadin Buddhism, the dominant form of the religion in Sri Lanka, Thailand, and Burma. Alternative versions of the same texts, known as the Agamas, were set down in Sanskrit and survive in Chinese translation. Both recensions include three collections: the Discourses (suttas or sutras) which describe accounts of the Buddha’s teachings; the Monastic Code (Vinaya), which recounts both the rules and the occasions on which they were formulated; and analyses of the mind called the Abhidhamma/Abhidharma. All these texts (as well as the much later scriptures of Mahayana Buddhism) purport to record the Buddha’s words, but the Discourses – or at least their oldest stratum – have the strongest claim as reliable historical records.

Most historians tentatively place Gautama’s birth in c. 480 BCE, (Bechert 1991/1992/1997) around 100 years later than the traditional date used by Theravadin Buddhists: the uncertainty reflects the uncertainties of early Indian chronology in general. Gautama was a member of a clan called the Shakyans whose territory, called Shakya, was on the northern edge of the burgeoning civilization of the Central Ganges Valley. The major nations of the Ganges civilization were Magadha, on the southern shore of the river, and Kosala, ruled from Shravasti, which held suzerainty over Shakya. Gautama was born in Lumbini, which is now in southern Nepal, but his mother, Maya, died a week after his birth. He was brought up in Kapilavastu, by Suddhodana, his father, and Maya’s sister Prajapati, who was both his aunt and his stepmother.

Legendary accounts of the Buddha’s childhood make Suddhodana a king who secluded his son (who they call Siddhartha) in a sumptuous palace to shield him from knowledge of suffering. The account in the early sources is sparser and less romantic, and as Shakya was a dependent clan republic, Gautama cannot have been a prince. However, he had a comfortable, probably aristocratic upbringing. The tradition that he married is strong, though we do not know the name of his wife, and we also hear of a son called Rahula.

These later accounts of the Buddha’s life also show him growing up in a society dominated by Brahmins and their Vedic religious traditions. However, the Discourses represent the Brahmins as new arrivals from the West and show that the Ganges Valley had its own indigenous religions. Popular religion focused on spirit shrines, while the most prominent full-time religious practitioners were homeless wanderers called shramanas. Many shramana sects existed, including the Jains who survive to this day. Their beliefs and practices varied, but most believed in rebirth and karma (the ethical weighting that determines rebirth) and the need to escape repeated rebirth through some form of liberation or enlightenment. Shramana practices included self-mortification and probably meditative contemplation.

The Discourses tell us that aged 29 Gautama experienced profound disillusionment with ordinary life, left home, and became a shramana (though his actual age may well have been younger). Gautama’s aim was to understand and remove the cause of life’s sufferings thereby escaping the cycle of death and rebirth. To this end, he practiced meditation, perhaps following the traditions recorded in the Hindu Upanishads, and undertook self-mortification in the manner of the Jains (Mahasaccaka Sutta: *Majjhima Nikaya* 36 (I 246–7)). Finally, he adopted the novel method of examining his mind and learning to guide it. In time, his mastery was so complete that he could transform its deepest workings, and aged 35 (c.445 BCE), he sat down to meditate in the place that is now called Bodhi Gaya. He later said that he achieved the state of *Bodhi*, which literally means “awakening” but is usually translated as “enlightenment.” Henceforth, he referred to himself as “the Buddha,” which means “the one who has awakened.”

The Buddha crystallized his insights in the teaching that all experience arises in dependence on conditions (the teaching of “dependent arising”) (Pathamabodhi Sutta: *Udana* 1:1 (Ud 1)) and can be changed through ethical practice and mental development, especially meditation. This insight implied rejecting belief in a fixed, unchanging soul or essence to human

identity, which his contemporaries called *atman*, and in a divine power at the heart of the universe, which some of them called *brahman*. It also showed that everything in experience is impermanent and insubstantial and explained why it is unsatisfactory to ordinary human experience. The Buddhist practitioner confronts these truths and in realizing them finds a source of creativity and happiness.

As the Discourses are not arranged chronologically, we cannot reconstruct a narrative of the Buddha's life for the 45 years following his enlightenment. But they do show him traveling across the region and sharing his teaching (the "Dharma") with all who would listen. Many of those he addressed were fellow shramanas; indeed, his first teaching was addressed to former companions in Sarnath, near the Hindu holy city of Varanasi. These men quickly realized his teachings for themselves, but in other cases, his encounters involved engaging with the many philosophies and creeds the shramanas held. He also met and debated with Brahmins (the priests of the Vedic tradition) as well as speaking with ordinary people of all social strata and professions. Many of these people followed Gautama's example by leaving their household lives and adopting his version of the shramana lifestyle, while others continued in their previous lifestyles as householder disciples. It is also worth noting that the Discourses describe many encounters in which the Buddha fails to persuade or convince the people with whom he speaks.

The Kings of Kosala and Magadha, the regions' leading powers, reportedly became Gautama's disciples early in his ministry, and after several years, he made a base in Shravasti, Kosala's capital, where he met frequently with the Koslana King Prasanajit (Skt). Through teachings and debates, he developed his own soteriological system that included detailed descriptions of the mind, meditation practices, and a detailed path to enlightenment. These teachings and the encounters that prompted them are the subject matter of the Discourses.

The Discourses describe regular sessions in which the Buddha explained his understanding of reality and the practices that could enable

others to share it. He repeatedly emphasized that his teachings were not what we would call metaphysics, but guidance in how human experience works and how individuals can change in order to eradicate the sources of suffering and find liberation. The foundation of his path was ethics (*shila*), and for him, the ethical status of an action depended on the motivation behind it. Unethical or "unskillful" actions, as he called them, are those rooted in craving, hatred, and ignorance, while skillful actions are based in opposite mental states. Unskillful actions have harmful effects in the world and also upon the person who acts. These states condition or shape a person's future experience. In this way, the Buddha's ethical teaching was tied to a dynamic view of human experience (and hence psychology) as well as a system of practices for mental development.

Our knowledge of other Indian meditative traditions is too limited for us to be certain how much of the Buddha's teaching drew on preexisting practice and how much was his own. The Discourses include a few mentions of non-Buddhist shramana meditators, but they seem to have been relatively few. However, certain key features of his approach contrast with what we do know of others. For example, along with ethics, the foundation of the Buddha's path of mental development was the development of mindful awareness (*sati/smṛti*) of all aspects of experience. By paying careful attention, a practitioner learns to become aware of his or her body, feelings, and mental states as well as seeing their experience in terms illuminated by the Buddhist teachings.

Other distinctive features of the Buddha's approach to mental development relate to focused concentration. Firstly, he regarded meditative concentration as a natural function of the mind and did not associate it with metaphysical beliefs about *atman*, *brahman*, or the origins of the universe as we find in Brahmanical texts. He called these "speculative views" and argued that they preempted the meditator's capacity to see reality directly. Secondly, he emphasized the importance of states of progressively intense concentration called *jhana* (Pali) or *dhyana* (Skt.) and gave detailed instructions on how to enter and

progressing through these states. Some non-Buddhists seem to have practiced dhyana-based meditation, but the Buddha's teaching that they are impermanent and the meditator should not cling to them was his own. More broadly, Gautama encouraged his students to use a balanced effort, which was neither too forceful nor too lax, in developing their minds. Thirdly, the Buddha taught what he called "vipassana" practices in which the meditator reflects on an aspect of experience as he described it, such as its impermanence or insubstantiality, in order to gain direct insight into the truth of the description. This is the ultimate purpose of Gautama's meditative system, and the other aspects are means to achieving it.

The movement Gautama started was initially one shramana group among many, probably known as the Shakyaputras shramanas (Skt: "the sons of the Shakyan"). Like the Jain shramana community, it included both men and women, and the Buddha affirmed that women could gain insight just as men could. The traditional account relates that the Buddha was reluctant to ordain women, but most modern scholars conclude that this is not reliable. The early Shakyaputra community was probably relatively informal and unstructured, emphasizing a life of wandering and forest dwelling as well as periods of communal retreat. However, in time the Shakyaputras evolved into a distinctive community with its own rules, structures, and monastic centers. It is uncertain how far this process went in Gautama's own life, but the Discourses record tensions between those monks who favored life in the wilderness and those who favored settled monasticism. Novice monks and nuns learned to recite certain key Discourses meditated according to the Buddha's instructions and studied intensively with senior monks before setting off on their own.

Alongside the renunciates were householders who supported the monks and nuns, providing them with almsfood and robes. They also practiced the teachings for themselves to some extent, especially those relating to ethical conduct. The community of the Buddha's disciples seems to have grown considerably during his lifetime and

Buddhist tradition records that many of them became *arahants*, attaining a degree of awakening that meant they were assured of full enlightenment. Many of these individuals gathered followers of their own. The two chief disciples were Shariputra and Maudgalyayana (Skt.), and they are often depicted in Buddhist iconography flanking the Buddha himself. The Buddha's companion for the latter part of his life was his cousin, Ananda, who is said to have possessed a powerful memory with which he memorized Gautama's teaching.

The community of the Buddha's followers is called the Sangha (sometimes this term refers solely to the monks and nuns). Together, the Buddha, Dharma, and Sangha are called the Three Jewels of Buddhism, embodying its essential character, and the Discourses include many accounts of the Buddha's encounters with people who chose to become his followers by "going for refuge" to these Three Jewels and then living according to the values they express.

Both the Discourses and later tradition suggest that the latter years of Gautama's life were a time of difficulty. One tradition speaks of a split with a group within the Shakyaputra community led by a monk called Devadatta who was probably a strict forest renunciate. A second tradition describes the mass killing of members of the Buddha's Shakyan clan by the King of Kosala.

The Buddha's final year is described in great detail in the longest of the Discourses, called The Mahaparinibbana Sutta. It records his journey through Magadha, the leading Ganges Valley kingdom, as it prepared for a war against its northern neighbors. It then describes the Buddha's journey northward and depicts a life of meditation and teaching to groups of householders and Shakyaputra monks. Finally, he arrived in the provincial town of Kusinara and took ill after eating some infected food. There he died aged 80 in c. 400 BCE.

The Mahaparinibbana Sutta describes the elaborate ceremonies and devotional rituals that accompanied the Buddha's funeral followed by the division of his relics and the construction of ceremonial mounds (stupas) to house them. This suggests that even in his lifetime, the Buddha was

a figure of considerable religious significance for a much wider community than his immediate disciples and that his status as an Enlightened Buddha had a recognized place within Ganges culture.

The Vinaya records that the Buddha's arahant disciples gathered after his death in a cave outside the Magadhan city of Rajagriha for a meeting that became known as The First Council. There, Ananda recited the teachings he had memorized so that others could recite them in their turn, and a monk called Upali recited the Vinaya. While the traditional account cannot be accepted in all its details, it seems likely that a meeting of Gautama's senior disciples did occur shortly after his death and that this meeting established a system of recitation and aural transmission that passed the Discourses and the Vinaya on to subsequent generations.

By the end of the Buddha's life, the Shakyaputras were probably one of the leading shramana groups in the Ganges Valley, and they seem to have attracted followers from many other parts of Northern India as well. The Buddha himself seems to have been a respected and influential figure but perhaps no more than some other shramana gurus. However, in subsequent centuries his teachings were widely recognized as a powerful and original alternative to both Brahminism and Jainism, and they became a central part of religious life across India following the conversion to Buddhism of the Mauryan Emperor Ashoka (304–232 BCE).

In a broad perspective, Buddhism in the West is just another phase in Buddhism's cultural migration, spanning more than 2,000 years. It also, however, constitutes a significant contribution within this history, sometimes referred to as a whole "New Buddhism," a "new Buddhist vehicle." Buddhism in the West comprises different types of groups, practices, and ideas related to the religion Buddhism, being geographically limited to Europe, North America, and in a broader sense countries outside of its Asian origin (South Africa, Australia, South America). This entry gives a historical overview of how Buddhism became part of the Western religious and cultural sphere, then discusses definitional and typological challenges, and finally explores the relations of science and Buddhism in the West.

Transplanting Buddhism from East to West: A Historical Overview

Alexander the Great's presence in Northern India was the context for the first meeting of Buddhism and the West. Westerners (Greeks) were mentioned in Buddhist sources (*Majjhima Nikaya* and *Milindapanha*), Buddhist Gandhara art was highly influenced by Greek art, and the first Western convert to and missionary of the religion (Dharmarakshita, third century BC) was probably a Greek descendant of the colonialists. Just like Alexander was never directly mentioned in the Indian classics, his Indian "counterpart," the first Buddhist king Ashoka, has not been mentioned by Greek historians, nor have the Indian stories of his missionaries being sent to the Mediterranean area.

Notwithstanding the possible Buddhist influences on early Christianity (especially Gnosticism), speculations of Buddhist monks having been to Greece to influence Greek philosophers and Christian mystics (and Jesus) going to India to learn from the spiritual depths of the East have, especially in esoteric and new age groups, had a certain fascination. Fascinated were also some of the medieval traders, adventurers, and Christian missionaries dealing with a mental landscape and a religion far beyond the politically and religiously troublesome Islamic region. Like the Far East, Buddhism was to most Europeans mainly an exotic other, if, to the majority, interesting at all.

Although having been discovered by intellectuals and missionaries already in the sixteenth century, it was not until the Enlightenment and later Romantic period that a true meeting between Buddhism and the West was realized. Rationality, religious criticism, and a search for human sources of truth claims were part of the Enlightenment project. Though Indian religions did not get the same recognition as the idealized Chinese Confucianism, the same ideals, however, were transferred also to Buddhism, when it was discovered in the first half of the nineteenth century. In the later Romantic period, rationalization was counterbalanced by an idealization of

feelings, experiences, mysticism, and origins, and romantics ascribed such ideals to be quintessential for Indian religions. Especially from the latter part of the nineteenth century, Buddhism became known as both a highly rational and spiritual path for literates, intellectuals, poets, scholars, and spiritual seekers. Such "rationalization" and "spiritualization" were due not only to the religion itself, in many ways being of a specific *kind* in the history of religion, but also to the history of its reception among scholars and practitioners and the cultural and political context of colonization.

Collecting the parts of hitherto heterogeneous sources to a whole more or less homogeneous religion was possible not the least due to philologists and scholars of religion, and when Eugène Burnouf (1801–1852) had his *Introduction à l'Histoire du Bouddhisme* published in 1844, a new religion was revealed for Western scholars. English, German, Scandinavian, French, Russian, and later American (and eventually from all over the world) scholars took up the task, and with the Pali Text Society, founded in 1881 by Rhys Davids (1843–1922), Buddhism as a textualized religion was established and later categorized as a world religion. The "historical Buddha" was identified, texts became canonized, and different lineages and schools were related in a genealogical framework in which social Darwinists could reflect evolutionary ideals and perennialists could claim Buddhism to express universal depths. Constructionist and postcolonial scholarship has noted the hegemonic contexts of Orientalism, in which such "Western" and Christian ideas were developed. Not only was the East conquered and its religions described, domesticated, and controlled, "Buddhism" was also "invented" under unequal power relations, and the Protestant bias of doctrinal and belief-oriented, anti-ritual, anti-lived religion representations has since been revealed as reductionist and particularist. Early focus on doctrinal ► [Theravada Buddhism](#) as being the true and original source of later degenerate ► [Mahāyāna Buddhism/Vajrayāna Buddhism](#), "Lamaism," and lived "folk Buddhism" until a

few decades ago was also the implicit template for Buddhist and religious studies.

Such Westernized projections were also part of *fin de siècle* representations of Eastern religions in popular literature. Edwin Arnold's poetic account of the Buddha, *The Light of Asia* from 1879, has been published in more than 100 editions, and later idealizations of Indian philosophy, Zen spirituality, and Buddhist magic and mystery from the Himalayan region have had enormous influence on popular images of Buddhism up to the present. Philosophers have used Buddhism to think with, and later generations of thinkers, artists, and authors have contributed to representing Buddhism as both an intellectual and highly spiritual tradition.

To a certain extent, such Westernized perspectives can be ascribed also to Buddhism in the West as a practice religion, both as underlying paradigms and expressed concretely through individuals and networks of influential persons. Madame Blavatsky and Colonel Olcott in 1875 created the Theosophical Society. Beginning as an American group, it soon became an international organization, proclaiming the parallels between science, evolution, spirituality, and esoteric religions, which they found best represented in Buddhism. Importing concepts such as karma and reincarnation into their esoteric (primarily literary) world view, they had a decisive influence on both spiritualist groups (continuing up to present day's new age and spiritualization) and conceptualizations in general of Buddhist and Eastern religions. The Theosophical Society was influential in the Ceylonese Buddhist revival, not least triggered by Blavatsky's and Olcott's arrival and taking of Buddhist refuge on the island in 1880 and Olcott's writing of the *Buddhist Catechism* (still used in Sri Lankan schools today). Anagarika Dharmapala (1864–1933) was their theosophical “pupil” and later himself became one of the most influential leaders in postcolonial Buddhist nationalism and modernity. Also some of the first Western converts were influenced by or members of theosophical societies, such as the British (and first Western) monk Ananda Metteyya, author Edwin Arnold, judge Christmas Humphreys, the German monk

Nyanatiloka, and several of the members of the late nineteenth-century symbol of nationalist and international Buddhism, The Indian Mahabodhi Society.

Modernity paved the way for international networks, and especially Dharmapala and the Japanese Zen “missionary” D. T. Suzuki (1870–1966) were tremendously influential in exporting to the West a “Protestant” form of spiritual and rational Buddhism. This protestant form of modern Buddhism is opposed to and yet inspired by Protestantism, such as focus on texts, degradation of rituals, and priesthood status. Not least the latter's relations to the American philosopher Paul Carus (1852–1919) inspired a modern interpretation of especially Zen Buddhism being scientific. Suzuki's teacher Shaku Sōen (1859–1919) with Dharmapala and the Indian Hindu reformer Vivekananda (1863–1902) had notable success at the Parliament of the World's Religions in Chicago 1893, a prestigious arrangement itself indicating a rising consciousness of Eastern religions. While the first European lay Buddhist groups of the early twentieth century were primarily of Theravadin origin (and especially in the British scene based on colonial relations), USA much earlier had relations to Eastern [Mahāyāna Buddhism/Vajrayāna Buddhism](#). Influential Buddhist teachers and missionaries and a long history of Chinese and Japanese immigrants made both elitist Zen Buddhism and East Asian folk Buddhism parts of the living American Buddhist reality. While Asians continued gathering in local temples, the first Euro-American groups and centers were formed around Japanese masters and missionaries like Nyogen Senzaki (1876–1958) and Shigetsu Sasaki (Sōkei an; 1882–1945).

The Beat Generation of the 1950s and 1960s not only continued the nineteenth century's literary tradition of “thinking with Buddhism,” it also itself helped spark renewed interests into Buddhism as a living religion in the West. Post-war existentialism and counter culture, hippie alternative lifestyle and flower power, easier and cheaper transportation to the Eastern regions further developed access to Buddhism, and from the 1970s onward, a plurality of Buddhist groups of

different schools and lineages were established in America, Europe, Australia, South Africa, and South America. Soka Gakkai, led by *sensei* Ikeda Daisaku (1928–), has had quite a success in its spread outside Japan, being the only truly global Japanese Buddhist school. As part of the increased interest in spirituality, mindfulness or *vipassana* meditation has been established not just as a doctrinal ideal or singular meditation practice but as part of a broader movement itself, promoted and practiced by individuals such as Sayagyi U Ba Khin (1899–1971) and Satya Narayan Goenka (1924–). Especially since the Chinese invasion of Tibet in 1959 and the subsequent diaspora of Tibetans, the perhaps most significant phase of contemporary Buddhism in the West has been established. Westerners went to the Himalayas meeting Tibetan Buddhism; lamas such as Tarthang Tulku (1934–), Chögyam Trungpa (1939–1987), Sogyal Rinpoche (1947–), Kalu Rinpoche (1905–1989), and the primary symbol of Tibetan and global Buddhism, Dalai Lama (Tensin Gyatso, 1935–), came to teach and establish traditions in the West.

The relevance of Buddhist teachers in all Buddhist history has been important. Tibetan lamas; Japanese (like Eidō Tai Shimano, Shunryu Suzuki, Taizan Maezumi, Harada Yasutani, Shodo Harada), Vietnamese (Thich Nhat Hanh), and Korean (Seung Sahn) Zen *rōshis*; and ► **Theravada Buddhism** monks (like Buddhadasa or Sivaraksa) in modern times have been influential agents of transferring the religion to the West (and sometimes, through spiritualization, rationalization, and popularization in the West, rebounding back to the East). Also Euro-American Buddhists like Sangharakshita, Philip Kapleau, Robert Aitken, Michael Roach, Jiyū Kennett, Surya Das, Pema Chodron, Ole Nydahl, Joseph Goldstein, Sharon Salzberg, and Jack Kornfield have taught and interpreted Buddhism for a Western audience. Their significance as symbols of spreading the dharma in a new tune is paradigmatic for the new “turning of the Buddhist wheel.”

Seen in retrospect, the history of Buddhism in the West has evolved from a primarily literary inspiration of an intellectual elite with a Protestant bias to a more widespread practice

of lived religion in a socially engaged, re-enchanted, and spiritualized world including meditation and (especially within Tibetan Buddhism) religious rituals. From a focus on primarily (textualized) ► **Theravada Buddhism**, through Zen to Tibetan Buddhism and contemporary “mindfulness boom,” singular traditions have kept developing their own identities while also being part of transnational, ecumenical, and global Buddhism. Apart from the practicing Buddhists in the West, Buddhism as an inspiration for therapy, psychology, philosophy, popular culture, consumerism, and management strategies has long lost its monastic attire in the West.

Monasticism is only for the few, but temple Buddhism is important for the majority of Buddhists in the West, namely, the immigrants coming from Asia. Their history goes further back in the USA, where Asians as the “old immigrants” already in the early nineteenth century came as working migrants. Like their later (also European, Australian, and South American) counterparts, initial expectations of eventually returning gradually changed into permanent residence and diasporic consciousness of being in a new cultural settlement in which also religion (and Buddhism) has importance. New immigration laws in the US and most European countries opened up for waves of migrants and refugees from Vietnam, Sri Lanka, Laos, and Cambodia, and with their descendants and family reunification possibilities, the amount of immigrant Buddhists has many doubled. While still being a minority religion in most Western countries, immigrant Buddhists in all Western countries constitute the absolute majority (up to 80 %) of Buddhists. While many threads combine elements of the “Euro-American” Buddhist history, the plural immigrant lines make up a tradition in many ways being so distinct that it has caused theoretical and conceptual discussion of “the two Buddhisms,” i.e., the spiritually and philosophically interested Euro-American “convert Buddhists” and the immigrant, “ethnic” Buddhists from Asia. Apart from focusing upon historical and cultural aspects, such reflections also point directly to (the difficulties of) understanding and defining Buddhism in the West.

“Two Buddhisms,” “Buddhism,” and “Western Buddhism”

As a dichotomous pair, “the two Buddhisms” has mainly been used in American and European contexts to distinguish the Buddhism of those with Asian origin as opposed to the “Euro-American” Buddhism, also termed variously “immigrant” or “ethnic” versus “convert” or “white” Buddhism. Immigrant or “ethnic” Buddhism is generally characterized by focusing on Buddhism as a religion related to the tradition and culture of the origin. Language, rituals, and social and cultural activities at the temples point to ethnicity as a major identity marker, with gatherings and services expressing typical “cultural religion” with temple engagement primarily related to rites of passage and major festivals. Merit accumulation, devotion, “folk religiosity” (use of amulets, ancestor worship, divination, etc.) and “other-worldly Buddhism” are as typical to ethnic Buddhism as a hierarchized gender and monk-lay relationship. Convert or Euro-American Buddhism is typically focused on meditation and philosophical readings of classical texts. It is typically individualized, psychologized, and spiritualized in focusing on a this-worldly, demythologized world. It is either de-ethnified in stressing the universal relevance of Buddhism or consciously “Westernizing” it by stressing the need for a more modern, democratic, egalitarian form of Buddhism (as, for instance, Sangharakshita, C. Trungpa, and Ole Nydahl have advocated for). That contemporary convert Buddhism to a large extent is a product of earlier Protestant Buddhism in a few cases is consciously acknowledged in Christianizing Buddhism (as, for instance, Jiyū Kennett and the Order of Buddhist Contemplatives).

That the dichotomous division, ethnic and convert, naturally can be criticized for its static nature is evident, and using two different classificatory taxonomies (ethnicity and religious conversion/engagement) as variables in a dichotomous pair does not make the logic of the typology more convincing. What about convert Buddhists not having ritually converted, some of whom might not even call themselves Buddhists?

What about the children raised as Buddhists, are they still converts, and how many generations does it take before immigrants are qualified not to belong to this category? Soka Gakkai started as a religion for ethnic Japanese but now almost exclusively is for converts, and most convert Zen Buddhists in Japan are actually the immigrants (from the West). Some convert Buddhists have taken interest in cultural aspects of Asian origin, often being more knowledgeable in Japanese martial arts or Tibetan culture than most Japanese and Tibetans. Some Vietnamese or Thais have been born into Buddhism but have actively taken interest in also elements of what typically constitutes “convert Buddhism.” Though also spiritualized and rationalized by some intellectuals, especially within Tibetan Buddhism in the West, offerings to heavenly beings, endless prostrations, belief in cosmic energies, miracles, or magical power transferred from lama to disciple through holy objects or bodily contact seem not that different from other kinds of traditional Buddhism in Asia. Is the main practice, chanting sacred words in front of an altar with a calligraphy scroll in order to acquire very concrete benefits of a very “modern” type of Buddhism, Soka Gakkai, in terms of belief and practice much different from many other traditional Japanese kinds of Buddhist belief and practice? Though democracy, gender equality, and egalitarianism are typical aspects of convert Buddhism, the strong commitment to the power, virtuosi, and charisma of Buddhist masters, lamas, *rōshis*, *senseis*, etc., in many ways seems to be identical not only to the worlds of new religious movements but also to the Asian context. The re-enchantment of the world might be a typical modern construct but often interestingly similar to enchantments of a traditional religious world.

Thus, empirical hybridity and terminological confusion have questioned the concepts, and other alternatives such as modern versus traditional or import versus export Buddhism have been suggested to capture the distinctions and relations between the kinds of Buddhism which, terminological confusion aside, still do seem in different degrees to exist in all Western countries.

Geographical origin and ethnicity as the dividing line is central, but not the only one in modern, Buddhism. Another is inter- and intrasectarian as well as the individual level, both pointing also to the question perhaps being more relevant for Buddhism than for most other religions: what *is* a Buddhist, what *is* Buddhism? Rather than using theological arguments in reaching an essentialist (but reductionist) delimitation, it might be more challenging to investigate the discourses and practices used within the diverse traditions, using a more pragmatic more or less family resemblance approach to capture (Western) Buddhism as a useful concept in the fluid and hybrid spectrum of contemporary individualized religiosity/spirituality.

Some are conscious of being Buddhist, are members of Buddhist groups, and might even have ritually taken the Buddhist refuges. Some hardcore Buddhists would claim a sharp distinction between being Buddhist or not and perhaps between being a true Buddhist (belonging to the right school, practicing or believing in an orthodox way) or not. Others use Buddhist ideas or practices (such as meditation), occasionally go to retreats or gatherings and might either do dharma (s)hopping, have a syncretistic mix of beliefs and practices, and might be reluctant (as Christian, Jew, spiritual seeker, atheist, or simply concept-detached individual) to call themselves Buddhists.

While believing, practicing, or being to the individual might be categories of determining authenticity, at an institutional, inter-, and intrasectarian level, legitimating tradition and authority is a matter of representation. Especially in convert Buddhist milieus, personal experience and legitimate transmission from former representatives of the religious institution are of utmost importance. Claiming the authority and authenticity of more or less charismatic “Western,” lamas, rōshis, and masters have often been a disputed topic, resulting in personal and institutional conflicts, as have disputes of which Buddhist groups might belong to “the Buddhist family.” Notwithstanding its fluid and hybrid character, *Western Buddhism* or *Buddhism in the West* is a useful umbrella category for the (just as hybrid and fluid) Asian Buddhism, having

been transplanted to another cultural and geographical hemisphere, including both convert and immigrants, and more or less Buddhists.

Science in Buddhism

Since its discovery in the West, Buddhism has often been related to discourses of science and the science of religion. Being described as “an atheist religion,” a “religion without God,” or simply as spirituality beyond the constraints of religion, Buddhism as an object became part of the enlightenment and modernity projects. Enlightenment thinkers and romantics could criticize religion and uphold versions of alternative truths by pointing to philosophical and textual versions of Eastern religious traditions (Confucianism, Vedanta, and later Buddhism) as evidence of their universal truths or placements on top of the religious evolutionary ladder. That modernist Buddhists such as Dharmapala, D. T. Suzuki, Chöphel, Taixu, Thich Nhat Hanh, and Dalai Lama have embraced science; that philosophers like Schopenhauer, Nietzsche, Heidegger, and Russell, scientists like Einstein, Bohr, and Bohm, and psychologists like Fromm, Jung, and Goleman were inspired by Buddhism; and that Western converts often have a general high level of education contribute to the image of Buddhism as a rational, intellectual, and even scientific religion, or “way of life.”

Whether there is actually a metonymical relation between Buddhism and science of course depends on the definitions of the concepts and the premises with which to operationally compare them. Do different contexts of origin, different methods and overall goals, and different semantic realms make them scientifically and Buddhistically incommensurable? Such theoretical discussions are beyond the scope of this article, but it should, additionally, be stressed that the “Buddhism” of “Buddhism and science” comprises only the very minority and elitist discourses and assumptions of primarily Western Buddhist modernists and that most Western scientists are reluctant to accept direct correspondence between science and Buddhism (or religion).

Most often, “science” in such contexts means the hard sciences and very seldom has a more “soft” scientific tradition such as sociology or interpretative methods within the humanities been related to or adopted by Buddhists as means of explaining its scientific value. This is due not only to the higher status of a presumably more “objective” science but also to the fact that critical approaches within the study of religion have a tradition of not only interpreting religious traditions “in their own languages” and at “face value.” Interpreting, explaining, and going beyond truth claims by also historicizing, culturalizing, and naturalizing them (including assertions of the scientific status of Buddhism) might not have the same appeal among Buddhists or Buddhist-inclined scientists, but is, however, a part of the history and study of Buddhism and science as well as Buddhism in the West. In this light, “scientific Buddhism” is also itself part of a theological and ideological discourse, legitimating and representing authority of (parts of) a religious tradition.

The following is a list of elements often used to explain the close relations between (or even identity of) Buddhism and science:

1. Buddhist approaches to epistemology and truth claims are based on a theoretical and philosophical basis of critical inquiry. Not accepting doctrines or absolutes for granted, there is a fundamental “hermeneutics of suspicion” in critically reflecting upon, exploring, investigating, and even deconstructing sources and representations of knowledge. Also classic world views (such as the idea of Mount Meru) have been either demythologized or simply discarded as nonscientific by modernist Buddhists. Buddhist classics, history, and contemporary rational arguments legitimate Buddhism as a “godless religion” and question whether it is a religion proper at all.
2. Buddhist ► **ontology** in its demythologized version is in accordance with modern physics. The underlying idea of the interrelatedness of all beings and things on the one hand relates to a holistic world view (combining person, nature, mind, body, subject, matter, concepts), while at the same time the idea of ► **impermanence** or emptiness of all things acknowledges a (postmodern) ontology of a fluid world being in concordance with both ecology and modern (quantum) physics.
3. ► **Evolution**, also in its Darwinian sense, is broadly accepted, since it does not interfere with a religion without creation – though it is also represented to be only a relative truth in a cyclic Buddhist cosmology with “many Big Bangs” and a karmic causality going beyond superficial meaningless and coincidental evolution.
4. Analyzing the person is of utmost importance to Buddhism, being the religion with the most developed and complex analysis of the self. Thus, Buddhist ► **psychology** has long ago acknowledged what Western psychologists (and postmodernists) have later incorporated into mainstream theory and templates for also therapeutic practice: the self as an impermanent, transient, fluid, and hybrid collection of interrelated parts. As a means of analyzing, controlling and transcending the “streams of consciousness” has ascribed to Buddhism the emblem “science of mind.”
5. Just as science, Buddhism is based on empirical investigations of causal relations and “reality as it is.” As opposed to other religions, truth claims may be transcended in order to get to “facts,” and as opposed to traditional science, Buddhists claim to go beyond (especially positivist) objectivist and interpretive/mediating methods by insisting on subjective experience as the profound epistemological approach to directly and fully realizing “how things are” and the causes and effects of all relations. Meditation (especially Vipassana, Dzogchen, and Zen) is often claimed to be such subjective means of scientific investigation, also being in accordance with (the findings of) newer forms of ► **cognitive science** and neurobiology.
6. ► **Postmodern** and post-essentialist notions of the dissolved self; of a fluid, relative, and decentered world; of relational and situational truth claims; of close interdependence between subject and object also in scientific investigations; of constructivist and relativist

world views; and of the breakdown of a grand narrative like the European Enlightenment can be legitimately argued from also a Buddhist frame of reference. With a typical dialectic of negation, even science and postmodernity – or Buddhism itself – can be transcended, thus both negating and affirming itself.

The relations between Buddhism and science have been institutionalized also academically in the West. Buddhism was an important tradition influencing the rise of the scientific study of religion, and both Asian area studies and Asian language studies in the West to a certain extent include also aspects of Buddhism in their curricula. Separate centers, institutes, research networks, or even universities focusing on Buddhist studies have emerged in the West, primarily in the USA. Also experimental studies within neuroscience and brain-scanning technology have involved experienced Buddhists in research projects measuring the impacts of meditation. The Mind and Life Institute with its dialogue between Buddhists and scientists is an example of such contemporary relations, involving also the Dalai Lama, who for many years has had interest in Western science. Such initiatives and his person itself have sparked further interest in the relations between Buddhism and science both among Tibetan (scholar) monks and Western scientists and converts, all contributing to a continuation of the image in the West of Buddhism as being a modern and contemporary robust religion.

Description

The coming into being of Buddhist canonical literature has its beginning point in what tradition reckons to be the word of the Buddha. Already this notion of the Buddha word, *Buddhavacana*, has a certain degree of complexity to it, since from earliest times it has included some discourses spoken by others, such as by disciples of the Buddha. According to a famous dictum, whatever is well said can be reckoned the Buddha's word (Morris and Hardy 1885–1900, IV, 164).

Regarding the verification of the authenticity of a particular text, the canonical texts indicate

that the central criterion should not be from whom a text purporting to be the word of the Buddha has been received in oral transmission. Rather, whatever squares with the remainder of the texts can be considered authentic (Morris and Hardy 1885–1900, II, 167). Another famous canonical dictum is related to the adoption of various vernaculars for the transmission of the sacred texts (Oldenberg 1879–1882, II, 139). In sum, these indications convey an impression of pragmatism and flexibility.

During the early centuries that saw the gradual coming into being of Buddhist canons, orality was the central mode for the formation and transmission of texts. Unlike oral literature of an epic or entirely narrative type, which involves innovation and improvisation, Buddhist oral transmission appears to have oriented itself along lines similar to its Vedic predecessors, which seem to have achieved an impressive degree of precision in the verbatim preservation of texts by oral means. Nevertheless, the natural vicissitudes of orality have certainly left their impact on Buddhist canonical texts.

In the course of time, the transmission of Buddhist canonical texts took place across a range of different geographical regions and in a number of languages, proceeding from orally transmitted material via manuscripts, xylographs, and eventually print, to modern day digital editions. Among Buddhist traditions nowadays there is no generally agreed single canon. Three particularly well-known canons can be singled out – respectively preserved in Pāli, Chinese, and Tibetan – although this means leaving aside the equally important material preserved in Sanskrit, as well as in a number of other languages, such as, for example, Gāndhārī or Khotanese.

- The Pāli canon of the Theravāda tradition (Buddhist Schools and Traditions), preserved in a language closely similar to, but not identical with, the Middle Indic language(s) the Buddha and his disciples would have spoken, was according to tradition transmitted from India to Ceylon by oral means and then committed to writing during the first century BC.
- The Chinese canon comprises a vast collection of scriptures that is the final result of

translation efforts that started shortly after the beginning of the Common Era and continued for more than ten centuries. Unlike the Pāli canon, the Chinese canon preserves scriptures stemming from different Buddhist schools and even multiple translations of single works, undertaken at different times. The undertaking and maintenance of this immense translation enterprise appear to have stimulated the invention of printing technologies.

- The Tibetan canon, similar in its vastness to the Chinese canon, is the product of translation efforts that began in the eighth century of the present era, covering various texts of Indian provenance. It follows a basic twofold division into *bka'* 'gyur, what tradition reckons as the word of the Buddha, and *bstan* 'gyur, commentaries and treatises, and has in turn been the basis for a Mongolian canon.

A basic structure of the Buddhist canonical collections, which has its roots in the early attempts to assemble the textual material into collections for transmission purposes, divides the material into three parts. These three parts are referred to as “baskets,” hence the term *tipiṭaka* or *tripiṭaka*, the “three baskets.” They comprise:

- Vinaya
- Sūtra
- Abhidharma

The basket that from an historical perspective probably contains the greatest share of early material is the second of these, the basket of discourses, *sūtra* (Sanskrit) or *sutta* (Pāli). The Pāli canon has four collections of such discourses, referred to as *nikāyas*. These contain discourses that have been placed together on the principles that they respectively are long, of middle length, share a particular topic, or are arranged according to a numerical scheme that ranges from 1 to 11.

The Chinese canon has preserved translations of similar groups of discourses, referred to as *āgamas*, although stemming from different Buddhist schools. Besides complete *āgama* collections, the Chinese canon also has partial collections and discourses translated individually, that is, on their own. Complete collections

comparable to the Pāli *Nikāyas* or the Chinese *Āgamas* are not found in the Tibetan canon, which only has few translations of individual discourses.

Comparison of parallel versions of these discourses, as they have been transmitted by various schools and often in different languages, shows the impact of oral transmission on the texts. In relation to content, parallel versions exhibit a number of variations, although these are mostly of a minor type that does not affect the basic meaning. Considerable differences can be found in the placement of discourses within the *nikāya* or *āgama* collections, however, clearly reflecting the fact that the principles for organizing the texts into units for transmission were applied in different ways.

The first of the three baskets is the Vinaya, which takes its origin from the various rules and regulations the Buddha is held to have pronounced for the sake of his monastic disciples. The framework of the Vinaya as a basket appears to have its origin in an attempt to place these rules into a historical context, both by presenting an account of the Buddha's mission in general as well as by providing a narration that purports to record under what circumstances a particular rule came to be promulgated and what type of difficulties led to later amendments.

The Pāli canon has preserved the Vinaya of the Theravāda tradition and the Tibetan canon the Vinaya of the Mūlasarvāstivāda tradition (Buddhist Schools and Traditions). The Chinese canon contains not only a translation of the Dharmaguptaka Vinaya, nowadays still observed by Chinese monastics, but also translations of a range of Vinayas of other schools.

Comparison of the different Vinayas shows close agreement in regard to the formulation of the rules for monks, but considerable variation when it comes to the accompanying stories and explanations. This suggests the rules to be the ancient core around which various stories and commentaries accumulated during the prolonged period of transmission.

The third basket contains the teachings of the Abhidharma, clearly reflecting developments in Buddhist philosophy that took place at

a considerable temporal distance from the Buddha's lifetime, perhaps beginning about the second century BC. The Pāli canon contains the seven books of the Abhidhamma of the Theravāda tradition, while the Chinese canon has preserved the Abhidharma of the Sarvāstivāda and other traditions (► [Abhidharma](#)).

The development of Abhidharma thought is not the only philosophical innovation that had its impact on Buddhist literature. Another movement resulted in a vast literature reflecting various aspects of Mahāyāna thought. Although often presenting themselves as "discourses," *sūtras*, Mahāyāna works stem from a time substantially removed from the historical Buddha, as is the case for tantric works.

Nevertheless, tradition sees the respective canons as the sacred record of the Buddha's liberating message, whose preservation keeps open the path to deliverance for those who are willing to follow his teachings. The actual study of the respective canonical collections, however, has until recently mainly been the domain of a monastic elite, whereas later works, often in the vernacular, came to fulfill a canonical function for the majority of followers of any particular Buddhist tradition.

Description

The approach to the subject of meditation in Buddhist thought can be characterized as thoroughly methodical and thus constitutes one of the aspects that place Buddhism in fairly close vicinity to scientific thought. The practice of Buddhist meditation and its medical effects have been investigated and studied for several decades, and the practice of mindfulness (► [Mindfulness \(Buddhist\)](#)) in particular has become a prominent feature in modern health care.

The Buddhist traditions have developed a range of meditation techniques. A comprehensive survey of such methods goes beyond the aims of this entry, as the theme of Buddhist meditation is rather broad, and several aspects of it receive coverage through other contributions to this encyclopedia (Chan, Zen). This entry will therefore focus in particular on two key aspects of mental cultivation in early Buddhist thought: tranquility and insight.

According to Buddhist meditation theory, the precondition for the development of tranquility and insight is the removal of the five hindrances of sensual desire, ill will, sloth and torpor, restlessness and worry, and doubt (► [Hindrances \(Buddhist\)](#)). Overcoming these hindrances depends on having established a foundation in ethical conduct and developing a sense of inner contentment.

When the hindrances have been removed, the gaining of deeper levels of concentration and insight comes within reach. The distinction drawn here between concentration and insight is not necessarily one of meditation methods, but rather one of complementary qualities. In fact, a meditation practice that from ancient times up to modern days has enjoyed particular popularity – mindfulness of breathing – could in principle be used for both purposes.

Undertaking of mindfulness of breathing requires remaining aware of the presence and nature of the breath, without attempting to influence it – unlike the case of breath control in other Indic traditions. When just observing the breath in this way, attention during meditation can be given to various phenomena related to

the process of breathing. Such a practice would stay in the realm of variegated sensory experience and thus be more geared toward the development of insight. In contrast, giving attention to just mentally knowing the presence of the breath would lead to a unitary type of experience and thus be capable of issuing in deeper levels of mental tranquility.

Other methods for gaining tranquility of the mind include cultivating mental attitudes of loving kindness, compassion, sympathetic joy, and equanimity. Alternatively, certain reflections can be used as the starting point of practice, such as recollecting the qualities of the Buddha, his teaching, and his awakened disciples. Buddhist meditation theory also knows of the use of meditation objects such as the four elements earth, water, fire, and wind, or colors like blue, yellow, red, and white. Each of these is first observed externally until the mind is able to produce an inner mental image that can then be used to deepen concentration.

This brief survey already reflects a considerable breadth of meditative approaches, and throughout the history of the Buddhist traditions the visual component has received emphasis, just as the conceptual and the experiential modes of practice.

Whichever of the above methods a practitioner may decide to employ, progress in matters of concentration should eventually lead to experiencing four levels of absorption (Sanskrit *dhyāna*, Pāli *jhāna*). These four absorptions are states of refined concentration that are accompanied by intense inner tranquility and happiness, culminating in a mental condition of total imperturbability and equipoise with the attainment of the fourth absorption.

When the fourth of these levels of absorption has been gained, according to Buddhist meditation theory it becomes possible to develop various supernatural powers, such as levitation and telepathy. Alternatively, the same degree of concentrative proficiency can be employed to develop four types of mental experiences that transcend matter. These are the concentrative attainment of the notion of boundless space, boundless consciousness, nothingness, and neither perception nor non-perception.

While the development of mental tranquility (Sanskrit *śamatha*, Pāli *samatha*) is an important aspect of the Buddhist soteriological enterprise, tradition holds that on its own concentration will not issue in liberation. What is required in addition to mental tranquility is the development of liberating insight (Sanskrit *vipaśyanā*, Pāli *vipassanā*).

The early textual sources leave it up to the individual in which way the development of these two chief qualities of tranquility and insight is undertaken. One type of practitioner may first emphasize gaining mental tranquility and then turn to insight, while another may begin with insight and only subsequently turn to tranquility, or else someone may develop both in conjunction (Morris and Hardy 1885–1900, II 157).

Training in liberating insight requires the bringing into being of seven mental factors singled out for their particular potential for ripening the mind for the decisive breakthrough to awakening. These are the seven factors of awakening, which comprise mindfulness, investigation of phenomena, energy, joy, tranquility, concentration, and equanimity.

The first of these, mindfulness, serves as the foundation for the growth of the other factors (► [Mindfulness \(Buddhist\)](#)). With mindfulness in place, the practice of investigating phenomena as they present themselves to the observing practitioner gains momentum which leads to energy and then to joy, qualities which with maturing practice find their counterbalance in tranquility and then concentration, leading up to a balanced state of equanimity.

What is to be apprehended by the meditating practitioner is the true nature of existence, that is, its nature of being conditioned and having three characteristics. According to these three characteristics, any aspect of conditioned experience is impermanent (► [Impermanence \(Buddhist\)](#)), unsatisfactory (► [Dukkha](#)), and devoid of a permanent self (► [Anattā](#)).

Here, the conditioned nature of subjective experience is a correlate to its impermanence, in that, precisely because something is conditioned, it must be impermanent. Conversely, what is impermanent is certainly a product of conditions.

With this basic understanding in place, the dynamics of insight proceeds from a thorough reviewing of the impermanent nature of all aspects of experience to the realization that what is impermanent cannot yield lasting satisfaction. With this realization, a growing sense of disenchantment comes about, weaning the practicing meditator from the innate tendency to cling and crave. Based on a thorough appreciation of the unsatisfactory nature of all aspects of experience, the conclusion then dawns on the practitioner that what is impermanent and unsatisfactory does not deserve to be reckoned as one's self and is not fit to be identified with. Developed in this way, insight into not-self becomes a prominent feature of meditative realization, this being the crucial insight in the Buddhist soteriological scheme.

Such meditative development of insight is held to lead to four distinct levels of awakening (► [Awakening](#)): stream-entry, once-return, non-return, and arahantship. The defining feature of these four levels of awakening is the degree to which the mind has been purified from detrimental conditions referred to as fetters, which "fetter" living beings to continued migration in the cycle of rebirths (and re-deaths). A stream-enterer has eradicated three such fetters – belief in a permanent self, clinging to rules and observances, as well as doubt – and is assured of reaching final liberation within at most seven lives. In other words, he or she has "entered" the "stream" that invariably leads to final deliverance.

The once-returner has diminished, and the non-returner has fully eradicated the two fetters of sensual lust and ill will. The once-returner will thus return only once more to be reborn in the sensual realm – a designation that in Buddhist cosmology comprises the human world as well as lower celestial realms in which refined forms of sensual pleasure are still experienced – while the non-returner will not undergo such a rebirth, being instead destined to rebirth in a higher heaven beyond the sensual celestial realms.

The arahant has also eradicated the remaining five fetters of desire for fine-material experiences, desire for immaterial experiences, pride, restlessness, and ignorance, thereby having gone

beyond future rebirth in any form. Although with the attainment of arahantship, Buddhist meditation practice has reached its culmination point; arahants still continue to practice meditation, apparently because for them this constitutes the best way of spending their time.

Caliphate

Eric Ormsby
The Institute of Ismaili Studies, London, UK

The institution of the caliphate, the principle form of governance in medieval Islam, had its beginnings upon the death of Prophet Muhammad in 632. The Arabic word *khalifa* (“caliph”) simply

means a “successor” or “deputy.” The term has Koranic warrant, as when God says to David, “We have made thee a *khalifa* in the land” (2:30). In this spirit, the earliest caliphs held the modest title of “successor to the emissary of God.” Since Muhammad had been “the seal of the prophets” – the final prophet in a line extending back to Adam – his successors were precluded from announcing further revelations. Nevertheless, their role was not entirely administrative and political; they served also as spiritual leaders of the Umma, or community of believers. The first four caliphs, beginning with Abu Bakr, the father-in-law and close friend of the Prophet, and continuing through ‘Umar, who launched the first waves of conquest beyond Arabia, and ‘Uthman, traditionally credited with the codification of the Koran, down to the troubled caliphate of ‘Ali, the cousin and son-in-law of Muhammad – and hence, his only male blood relative – represent an idealized golden age for Sunni Muslims; this was the period of the “rightly guided caliphs.” Shia Muslims reject this rosy view; they consider the first three caliphs as little better than usurpers of Ali’s rightful claim to the office. It says much about this earliest formative phase of the caliphate and the inherent tensions of succession that all but Abu Bakr died at the hands of assassins. In 661, the murder of ‘Ali led to the rise of the Umayyad dynasty. During the ensuing century, the Umayyad caliphs saw themselves less as successors to Muhammad than as “God’s caliphs,” and the status and power of the office swelled considerably. After the Umayyads

were overthrown by the Abbasids in 749, the caliphate took on even more exalted trappings. The Abbasid caliphate endured for five hundred years (750–1258) before being extirpated by the Mongols. During its first two centuries, the caliphs wielded enormous power. Their functions ranged from the launching of expeditionary forces, not only against such rival empires as Byzantium but against various rebels and malcontents within their territories, to the administration of government appointments, the levying of taxes, and the supervision of the judiciary and even, in their role as defenders of the faith, to presiding over the Friday prayer, conducting the pilgrimage, and safeguarding, as well as occasionally formulating, articles of dogma. The office had spiritual prestige as well as political authority; the caliph was the “imam” as well as the “teacher” of his subjects, and that prestige endured even after the caliphs themselves had lost real governing power.

The Abbasid caliphs were assiduous patrons of science, art, and culture; such patronage became a fixture of caliphal rule, not only among the Abbasids but in rival courts, such as those of the Fatimids of Egypt and Syria (909–1171), an Ismaili-Shia dynasty, or of the Spanish Umayyads (756–1031) in the Iberian Peninsula. Beginning in 754 with the Caliph al-Mansur, the Abbasids sponsored an ambitious “translation movement” to bring Greek (and to a lesser extent, Indian and Persian) scientific and philosophical literature into Arabic. The establishment of the *Bayt al-Hikma*, or “house of wisdom” in Baghdad, a rich library formed on an earlier Sasanian Persian model, led to the creation of a vast corpus of learning which was continually revised and refined for the next two centuries; in this process, most of the works of Aristotle and Plato, as well as of Galen, Ptolemy, and dozens of other ancient thinkers, appeared in Arabic versions. This in turn inspired original philosophical, medical, and scientific treatises in Arabic by such outstanding Muslim thinkers as Kindi, Razi, Farabi, and Ibn Sina and such mathematicians as al-Khwarizmi, Ibn al-Haytham, and al-Biruni, among others.

The caliphate endured as an institution even as it fell, increasingly after the tenth century, under the sway of emergent dynasties such as the Shia Buyids (932–1062) and, more decisively, the Seljuq Turks (1040–1194), whose sultans – originally vassals of the caliphs – became de facto rulers of the Abbasid realm. The terms “caliph” and “caliphate” continued to be used on occasion by various rulers, such as the Mamluk Sultans of Egypt and Syria (1250–1517) or the Ottoman Sultans. The title conferred the legitimacy of succession in a line extending back to the Prophet himself. In 1922, the Ottoman sultanate was abolished, and in 1924, upon the establishment of the Turkish Republic, the caliphate itself came to its official end. An idealized concept of the caliphate continues to resonate for militant Muslims, and the call to restore the caliphate has become a frequent rallying cry among jihadists.

Caloric Tests

Pedro L. Mangabeira Albernaz
Associação William House de Otologia and
Instituto Israelita de Ensino e Pesquisa Albert
Einstein, São Paulo, SP, Brazil

A functional evaluation of the external semicircular canals that use water or air to change the temperature of the canal ampulla. These tests were perfected and standardized by C.S. Hallpike (Hallpike 1955). There are five variants: (1) the bithermal test which is standard performance; (2) the monothermal test in which a single large bolus of ice water is given instead of two irrigations with hot and cold; (3) the bilateral irrigation test in which both sides are irrigated simultaneously; (4) the balloon test where a water filled balloon is used rather than water and (5) the ice water caloric test which is used to confirm complete loss.

cAMP and Memory

Jörg-Peter Ewert
Faculty of Natural Sciences, University of
Kassel, Schauenburg, Germany

Cyclic adenosine monophosphate, cAMP, is a *second messenger* used in intracellular signal transduction of a neuron (cf. Question-5). Synthesis of cAMP depends on adenylate cyclase which is activated by a G_s -protein-coupled

receptor at the postsynaptic membrane in connection with a neurotransmitter (*first messenger*) that is released at a synapse to the axonal ending of this neuron. cAMP in turn activates protein kinase A (PKA).

As regards short-term memory, PKA leads to a facilitation of neurotransmitter release from the axonal ending of this neuron (sensitization).

As regards long-term memory, PKA in the nucleus of the same neuron activates CREB protein as transcription factor that binds to a certain DNA sequence and thus increases the transcription of certain *CRE* genes. Members of the CREB family contain enhancers (CREB1) and repressors (CREB2) of transcription. Each one is activated by a protein kinase, the enhancer by PKA and the repressor by MAPK (mitogen-activated protein kinase). The actions of both protein kinases depend on the cAMP level. The CREB1/CREB2 balance then determines long-term memory associated with synaptic growth by axonal sprouting at the synapse of that neuron. This allows facilitation of synaptic transmission to persist (long-term sensitization).

Canonical Neurons

Giacomo Rizzolatti and Maria Alessandra Umiltà
Dipartimento di Neuroscienze, Sezione di
Fisiologia, Università di Parma, Parma, Italy

Canonical neurons are a specific class of neurons of the monkey ventral premotor cortex that discharge during motor act execution and in response to the presentation of 3-D objects. Typically they show congruence between the motor acts they code (e.g., precision grip) and the physical properties of the observed object (e.g.w, small object).

Cardiology

Marc W. Merx and Malte Kelm

Department of Cardiology, Pneumology and Angiology, Universityhospital, Heinrich-Heine-University Duesseldorf, Duesseldorf, Germany

Related Terms

[Circulatory system](#); [Heart](#)

Description

Cardiology is the medical discipline dealing with the heart, its functions, and its diseases.

During the course of the twentieth century, cardiovascular disease became more prevalent, especially in the industrialized nations, due to more sedentary lifestyles and altered diets (industrially refined, fat and sugar rich). In addition, the introduction of antibiotics toward the middle of the twentieth century curbed the death toll due to infection, hence extending life expectancy and increasing the likelihood and thus frequency of cardiovascular disease. These ongoing processes have led to an ever-increasing number of patients seeking the attention of cardiologists, a trend expected to carry on well throughout the next several decades.

With the first balloon angioplasty of a coronary artery performed by Andreas Gruentzig in Zurich in 1977 paving the way, Cardiology has been enriched by decidedly interventional treatment options. Especially the past two decades have seen the development of various interventional treatment approaches not limited to coronary artery disease but also encompassing structural and valvular heart disease as well as heart rhythm disorders with a major impact on the way Cardiology is practiced today (www.escardio.org).

Self-Identification

Science

Natural scientists and physiologists have been attracted to the heart and circulatory system for

centuries with W. Harvey first describing the essentials of the mammalian cardiac function and circulation in 1628. Arising from this, Cardiology is firmly grounded as a natural science, which sees itself as a scientific endeavor with the aim to enhance the knowledge about the organization and function of the human cardiovascular system as well as its disease-related abnormalities. This aim of enhancing knowledge in the fields of cardiovascular function as well as the fields of diagnosis and treatment of cardiovascular disease is strived for through rigorous basic research as well as by implementation of clinical trials. The best of the latter are designed to be randomized, blinded, placebo controlled, and externally monitored whenever possible.

Characteristics

Cardiology distinguishes itself from other disciplines in many ways.

It involves the treatment of cardiovascular disease which has been the most frequent cause of death in Europe and other industrial nations for several decades. Due to advancements in the therapeutic developments in Cardiology, this death rate is steadily decreasing.

The physiological and pathophysiological processes studied and treated in Cardiology are of a mechanistic nature compared to most other areas of medicine. For example, in valvular heart disease, a given heart valve can either be too tight (stenosed), allow a backward flow (regurgitant) or be characterized by a combination (to various degree) of the two phenomena. The mechanical obstruction or dysfunction can then be treated by catheter-based dilatation (valvuloplasty) in the case of stenosis or by catheter-based adaptation of valve leaflets in the case of regurgitation.

With the increasing possibilities of interventional cardiology the sister-disciplines of Cardiology, namely, Cardiothoracic Surgery and Cardiovascular Surgery, are merging together in providing optimal therapy for the individual patient in a fashion and extent unprecedented in medicine, thus clearing the vision for new therapeutic perspectives to the great benefit of patients

with cardiovascular disease (www.dgkardio.de; www.heart.org; www.acc.org).

Relevance to Science and Religion

While Cardiology and cardiovascular science are very productive fields of science, the interaction with religion has been minimal.

Nevertheless, the heart is important in the human collective psyche. Even before the time of Romeo and Juliet, the heart has been synonymous with love, a central aspect and theme of a large number of religions. Furthermore, in the English language, and other languages, the heart is frequently used to describe emotions (e.g., heartfelt, heavy heart, change of heart, “Herzschmerz”).

Sources of Authority

Today, the authorities in Cardiology are various departments and cardiologists whose origins date back to William Harvey, who in 1628 first described the circulatory system in mammals. One of the first prominent cardiologists in clinical medicine was Jean Nicolas Corvisart (1755–1821) who, after training in Vienna, practiced at the Hospice de la Charité in Paris. His important publication “Essais sur les maladies et les lesions organiques du coeur et des vaisseaux” (Essays on the disease and organic lesions of the heart and circulatory system), published in 1818 already covered pivotal aspects of Cardiology such as structural heart disease, valvular heart disease, and heart rhythm disorders with the interesting omission of coronary artery disease/ischemic heart disease. One of his successors in Paris, Rene Theophile Hyacinthe Laennec (1781–1826), took great interest in cardiac auscultation and is credited with inventing the first dedicated stethoscope (Lichtlen 2002).

Among the early authoritative texts in cardiology was that of Heinrich von Bamberg (1822–1888) published in Vienna 1857, “Lehrbuch der Krankheiten des Herzens” (Textbook of Diseases of the Heart). A further important textbook was “Traite Clinique de Malades du Coeur et de

l’Aorte, Tome II. Maladies des Coronaires et de l’Aorte” (Clinical Papers on Diseases of the Heart and Aorta) by Henri Huchard (1844–1910) published in Paris in 1899 (Lichtlen 2002).

Contemporary textbooks in cardiology have predominately originated in the USA with “Braunwald’s Heart Disease” and “Hurst’s The Heart” being the two most prominent examples.

Ethical Principles

Cardiology is, as is every discipline in medicine, ethically guided by the oath of Hippocrates, the Greek physician and “founding father” of medicine born 460 BC. More recently, this oath has been revised under the rules of the Declaration of Helsinki of 1971.

Key Values

The key value of Cardiology can be found in improving a patient’s cardiovascular health status. This is frequently achieved in acutely life-threatening medical conditions necessitating permanent (24 h/7 days/365 days a year) availability as well as rapid accessibility of cardiology services (optimally within minutes) for every individual of any given population.

The gratifying value of Cardiology to those practicing this discipline is the fact that the duration and the quality of life can be increased significantly for a large number of patients.

Conceptualization

Nature/World

Nature can refer to the physical world including the environment and life in general including the personality. Therefore, it could be said that nature is connected to the heart through the personality.

Human Being

The human being is a member of any of the races of *Homo sapiens*, living or extinct.

Life and Death

Life can be described as the property or quality that distinguishes living organisms from dead organisms and inanimate materials. It is considered to be the interval of time between birth and death.

The heart is one of the first organs to assume function within embryonic development with pulsatile activity discernable as early as day 22 of pregnancy.

On the other side of life's spectrum, death is frequently equated to the cessation of heart beat. While this definition of death is not correct medically, it is very widely spread across different cultures and populations and has been factually correct in nearly every case over several thousand years of humanity except for the last few decades.

Modern cardiologists often deal with patients who are resuscitated, thus blurring these seemingly in-permeable boundaries of life. Patients who have been resuscitated from circulatory/cardiac arrest often describe so-called near death experiences. These are frequently described to encompass multiple possible sensations including detachment from the body, total serenity, and the presence of a light.

Reality

Reality is classified as that which exists objectively and in fact.

Knowledge

Knowledge is the awareness, consciousness, or familiarity gained by experience or learning. Knowledge that can be produced by an individual from memory or intuition without consultation of external sources (other humans, books or any written form of information, audio or video files) is often referred to as "to know by heart."

Truth

Truth conforms to fact and actuality. It is a comprehensive term and in all of its nuances implies accuracy and honesty. "Veracity is the heart of morality" (Thomas H. Huxley).

Perception

Perception is the awareness and knowledge of any force, influence, or other sensation through the senses, especially sight and hearing.

Time

Time is an interval separating two points on a nonspatial continuum in which events occur in apparently irreversible succession from past through present to future. In Cardiology the measurement of heartbeats per minute is of extreme importance. Interestingly, the predominant heart rhythm observed in humans, so-called sinus rhythm has a normal range in adults at rest between 60 and 90 beats/min. This implies that in many situations (i.e., whenever the heart rate is 60 beats/min) the interval between two heartbeats equals 1 sec, the international unit of time.

Relevant Themes

With respect to "Science and Religion" a critical issue in Cardiology lies in organ transplantation. General ethical questions related to organ procurement and distribution have been addressed by several organizations such as the World Health Organization (www.who.int/ethics/en/EB113_14) and the European Commission. Most of the world's religions support organ as a charitable act with the respective community gaining great benefit. While Jehovah's Witnesses are frequently assumed to be strictly objecting to donation due to their belief against blood transfusion, the latter rather means that all blood must be removed from the organs and tissues before they could be transplanted.

Despite this benevolent position of the world's religions toward organ donors, the decision to donate the heart, be it by surviving relatives or by the donor himself, remains emotionally and spiritually charged compared to kidney or lung transplants. Likewise, the recipients frequently describe feeling a special connection toward the (in most cases) unknown donor.

Cartesian Conception of the Mind

Karsten R. Stueber
 Department of Philosophy, College of the Holy Cross, Worcester, MA, USA

This term refers to the conception of the mind that originated with René Descartes (1596–1650). More generally, it refers to a conception of the mind that gives primacy to the first-person perspective in discussing issues about the nature of mental states and mental concepts. For a Cartesian, mental state concepts are, for instance, defined in regard to experience to which each of us has access only introspectively. Cartesian dualism then refers to the distinction between the mind as an immaterial, nonphysical concept and the brain as a physical, measurable entity.

The Science-Catholicism Relationship from Vatican I to Vatican II

All through its history, Roman Catholicism has managed to come out of serious crisis situations with considerable success. One of the secrets of this remarkable resilience can be traced to its tradition of convening ecumenical councils which are very special events wherein bishops and other top leaders of the Church from all

over the world, under the leadership of the Pope, come together to deliberate on critical issues and take appropriate steps to deal effectively with them. The Catholic Church recognizes 21 ecumenical councils starting from the first one in Nicaea in 325 AD to Vatican II in 1962–1965. Of these three are identified as the modern era councils: the Council of Trent (1545–1563), Vatican I (1869–1870), and Vatican II. In what follows, I offer a critical study of the documents of the last two councils from their historical, religious, scientific, and philosophical context. Special effort will be made to discuss critically the impact of sciences in necessitating these councils, shaping their different decrees and declarations, and even guiding many important aspects of their course. In fact, it is important to note that these two were the only councils that took place after the advent and development of modern science and hence had to face the full weight of its influence.

The First Vatican Council

Various developments in science and related fields played a crucial role in posing a serious challenge to the Catholic Church to which it had to respond. Not only individual theories, discoveries, and technological developments, but, even more, the worldview shaped by science and the wide impact it had on various fields of human thinking and living offered a serious challenge to traditional Catholicism. Space constraint compels me to confine discussion to only a few of these developments. This discussion is intended to shed light on the key themes related to Vatican I, particularly Pius IX's Syllabus of 1864 and the two principal documents of the Council, both of which had as their target a number of "errors" arising from developments in science.

Developments in Science, Philosophy, and Related Areas

Mechanical Philosophy of Nature. Mechanical Philosophy of Nature (MPN) resulted from the unprecedented success of science from the seventeenth to the end of the nineteenth century.

MPN looked upon this whole universe as a gigantic machine governed by the principles and laws of Newtonian mechanics. All living beings, including the human body, were also reduced to complex machines. In its extreme form, MPN claimed that all phenomena of our experience, including thinking, sensing, reproduction, etc., could be explained mechanistically. Science could give knowledge that was absolute, certain, exact, and objective. It projected science as the superpower that could accomplish everything, rendering God dispensable. Laplace's reply to Napoleon that the God hypothesis was unnecessary to explain the functioning of the universe was a clear demonstration of this attitude. Scholars like Michael Buckley have traced the roots of western materialism to this worldview. By making the empirically validated scientific knowledge the paradigm of valid knowledge, it began debunking knowledge that could not be subjected to empirical testing, particularly religious knowledge.

The Industrial Revolution. The Industrial Revolution was another consequence of scientific developments that transformed the mode of living and thinking of humankind mostly from 1750 to 1850. It brought about a mechanization of industry and mass production of commodities. Socially, it gave rise to a shift from an agrarian and rural to an industrial and urban society. Dependence on erratic nature, and hence on God and religion, decreased, and reliance on science and technology increased. Consequently, the Church and related activities began moving away from its traditional central place to the periphery. Material prosperity, better knowledge, and greater independence naturally led to liberal perspectives and ideologies along with a critical attitude toward traditional beliefs, values, and structures. These developments influenced considerably the official documents of Vatican I.

The Ghost of the Galileo Episode. Galileo failed to give convincing evidence for his support of heliocentrism at the time of his condemnation in 1633, even at the time of his death in 1642. However, it came in the middle of the nineteenth century, a few years before Vatican I. First, the Foucault pendulum, a simple device to

demonstrate the daily rotation of the Earth, was invented by Leon Foucault in 1851. Second, the ingenious observation of stellar parallax, the observed apparent motion of a star due to the real motion of the Earth, gave evidence for the revolution of the Earth around the Sun. This controversy had significant bearing on Vatican I because of the central importance it gave to Papal Infallibility. Although the Church's official condemnation of heliocentrism did not go directly against infallibility, for the critics, it considerably weakened the claim of the Church authorities that they had privileged divine illumination concerning truths.

Darwin's Theory of Evolution. Darwin's theory of 1859 that the different beings in the universe appeared gradually as a result of a long and complex evolutionary process questioned the traditional teaching of the Church on the origin of living beings, especially humans, and it challenged the reliability of scripture, particularly in its literal interpretation. It was also a very attractive illustration of naturalistic explanation which attempted to dispense with any divine role in the creation of life and intelligent beings.

The Enlightenment. The Enlightenment, an eighteenth century European philosophico-cultural movement, was characterized by an emphasis on reason, especially scientific reason, based on concrete data and logical method, and a strong dislike for tradition. While overvaluing empirically observable facts, it tended to devalue religious claims based on faith and authority. It was very clear that the overall effect of this movement was the gradual unseating of traditional religion with its emphasis on faith and the spiritual, replacing it with tangible reason and practical success.

Positivism. Positivism held that all true knowledge must be based on sense experience and accorded a preeminent place to science and scientific method. The development of positivism by Auguste Comte, undercutting the importance of the religious, in the middle of the nineteenth century, just a few years before Vatican I, contributed considerably to the devaluation of religious faith and dogmas.

Marxism. Karl Marx in mid-nineteenth century mounted a scathing criticism on Christianity, describing it as "the sigh of the oppressed creature, the heart of a heartless world, and the soul of soulless conditions. It is the opium of people." Far from being an answer to human problems, for him, religion was part of the oppressive system. These ideas also posed a formidable challenge to the Church at the time of Vatican I.

Rationalism and Naturalism. Rationalism and naturalism were highly influential views in the mid-nineteenth century. Rationalism assigned primacy to reason, reducing divine revelation or any other supernatural source to insignificance. For naturalism, the natural world of science was all that counted, thereby dispensing with any recourse to the supernatural. The spread of these two philosophical positions was also a major concern of Vatican I.

Developments in the World of the Catholic Church

Gallicanism and Febronianism. Gallicanism, a French ecclesiastical and political doctrine and practice, recognized the Papacy as a divine institution but stood for curtailing papal influence in the temporal field. Given the complexity and volatility prevalent in Europe for centuries, it is clear that this movement was a source of constant tension for the Pope as a person and the Papacy as an institution. Febronianism basically was the German counterpart of Gallicanism.

Ultramontanism. Ultramontanism was the opposite of Gallicanism and advocated papal supremacy and the centralization of the Roman Curia. The Jesuits, with their fourth vow of special loyalty to the Pope, were staunch supporters of this view.

The Papal States and the Challenges of Pius IX. The Papal States were the territories that were under the temporal sovereignty of the Papacy. They included parts of Italy and Avignon Venaissin in France from 756 to 1870. With the rise of strong nationalism in Europe, the Pope began losing these territories and finally was left with a small territory of the Vatican City and its vicinity. All these developments had a profound impact on Pius IX, who began his pontificate in

1846 as a sympathizer with the liberals. However, the bitter experiences of later years forced him to change his attitude. Particularly devastating were the Revolutions of 1848 and their aftermath. This period proved to be one of unprecedented disasters for the Pope. He was stripped of his political powers, forced to flee Rome in disguise, and became a “prisoner in the Vatican” when he managed to come back in 1850. Although Pope Pius IX’s person and reign were matters of serious controversy, even his critics admit that he placed the good of the Church before everything else. He was convinced that the new trends and developments like rationalism, naturalism, liberalism, etc., were utterly harmful to the Church and humanity. He was determined to fight back with all the powers he could muster. The firm, strong, and uncompromising steps he took in the ensuing years were to be seen in this complex context. He fought back first by promulgating the *Syllabus of Errors* in 1864 and then calling the First Vatican Council in 1869.

The Syllabus of Errors. The *Syllabus of Errors*, which was 12 years in preparation with 80 items, could be considered the preface to Vatican I since it provided most of the ideas discussed at the Council. Scholars like T. Tackett think that Pius IX convened Vatican I to obtain conciliar confirmation for the *Syllabus of Errors*. The whole thrust of this document can be summarized into two tendencies both of which were strongly condemned: the downgrading of God and the divine and the upgrading of nature and the natural. Pope Pius IX considered Vatican I as a decisive step to counter firmly this powerful threatening current.

Chronology of the Events of Vatican I. According to some scholars, already in 1849, Luigi Cardinal Lambruschini, a member of the Roman Curia, suggested convening a council to Pius IX. The Pope himself mentioned its possibility in 1864, but the initial work started only in 1865. The formal announcement was made in 1867, and the apostolic letter of convocation was given on 29 June 1868. The first session started on 8 December 1869. The first voting on infallibility was on 13 July 1870, and Pius IX

suspended the council indefinitely on 20 October 1870.

The Documents of the First Vatican Council. This council approved two dogmatic constitutions: *Dei Filius*, “On the Catholic Faith,” and *Pastor aeternus*, “On the Church of Christ.” The first talks about the precarious and alarming situation caused by the rise of rationalism and naturalism. These false doctrines have led people to “the abyss of pantheism, materialism, and atheism,” resulting in the destruction of rational nature, denial of any genuine criterion of what is right and just. They question the supernatural origin and destiny of the Church, the Magisterium, and the Teaching Authority of the Church and the importance of Holy Scripture and sacred tradition, and reduce religious questions to a matter of individual judgment. With regard to the source and interpretation of Holy Scripture, it affirms the traditional view of direct divine origin and the official Church as its only authentic interpreter. Reason and faith, it sees as a twofold order of knowledge, which, though distinct, do not conflict since both have God as their source. Matters of faith cannot go against reason because they are confirmed by miracles and prophecies. It affirms the Catholic Church as the sole custodian of Christian faith, the divinely ordained arbiter of what is right and wrong. Hence, Christians are “forbidden to defend as legitimate conclusions of science those opinions which are known to be contrary to the doctrine of faith.” Coming to dogmas, it asserts that they are part of the immutable divine deposit, and hence, their meaning must be maintained intact.

Pastor aeternus, “On the Church of Christ,” had its focus on the jurisdictional primacy and infallibility of the Pope. The major part of this document dwells on the Primacy of Peter and of the Pope as his successor. It may be noted that although Vatican I is known for its definition of Papal Infallibility, this point came up strongly only toward the end of the Council; but once it came up, it became the epicenter of heated debates. Just before the final vote, more than 60 members left Rome, and when the final vote was taken, 533 voted for and 2 against.

Since the impact of science on this document seems to be very limited, we will limit ourselves to giving the final statement of the dogma of Papal Infallibility, which says: When the Pope speaks *ex cathedra*, in his office as shepherd and teacher of all Christians, on doctrines concerning faith or morals to be held by the whole Church, “such definitions of the Roman Pontiff are of themselves, and not by the consent of the Church, irreformable.”

Some Remarks

The Language of the Texts. The language of the texts is clear, direct, and absolute, leaving no room for doubt or misunderstanding, dialogue, or compromise. All major assertions are followed by “*anathema sit*,” “let him be anathema.” Today’s democratic and dialogical world may find such an approach jarring, particularly in a religion that considers love and forgiveness its characteristics marks. However, when we consider the nature and purpose of the text, the circumstances in which the whole developments took place, as given in our detailed background study, this style and tone becomes understandable.

Science and Vatican I. The impact of developments in science and related fields on Vatican I is very evident in the documents. Many of the decrees and affirmations of the council are targeting scientific ideas and certain ideologies that emerged from them. Vatican I for the most part took a negative, narrow attitude to these developments, perceiving them as harmful to the Church and humanity. It seems to me that this situation led scholars like Andrew White and John Draper at the end of the nineteenth century to the conflict model for the science-Catholicism relationship. Although this may, in some ways, be true during this period, when we consider the wider period from the beginning of modern science to the present day, the relationship is far more complex. For instance, when modern science was in its infancy, the Church encouraged and supported it. As we shall see, Vatican II took a positive and collaborative approach toward modern science.

The Second Vatican Council

Features of the Council

Vatican II was, in many ways, a landmark in the history of the Catholic Church. According to the Apostolic Brief, *In Spiritu Sancto*, “The Second Vatican Council. . . must be remembered without doubt among the greatest events of the Church.” Not only did many new ideas emerge from it, but also a new approach and a new attitude arose as a consequence of this largest ever ecumenical council. As Oscar Cullmann observes, the impulses of this council are as effective as its documents. Many of its novel and revolutionary ideas and path-breaking approaches are yet to become an integral part of the Church’s official policy and practice.

Vatican I and Vatican II. Since Vatican II follows serially Vatican I, one is understandably tempted to consider it as a follow-up on Vatican I. But a serious reflection on these two councils reveals that they were significantly different. For instance, Vatican I was very much institution-centered, whereas Vatican II was conspicuously people-centered. The primary move of Vatican I was principally to conserve and confirm, while that of Vatican II was mainly to preserve and progress. Vatican I focused on defining certain dogmas to bring clarity and conformity, whereas Vatican II focused on updating Catholic teaching and heritage to make it more relevant to the times. With regard to science and technology, Vatican I made very few references, mostly to show their negative impact, while Vatican II addressed the subject of science and technology quite frequently, mostly in a positive tone. As Giles Routhier points out, many Council Fathers, particularly E.A. Blanchet, Rector of the Institut Catholique of Paris, and P. Veuillot, Coadjutor Archbishop of Paris, wanted to give “positive praise to its great dignity.” Vatican I was conspicuous in its use of the language of condemnation and “*anathema sit*,” whereas Vatican II wanted to use the “*medicine of mercy* rather than of severity.”

Although the exact causes of this striking turnaround is difficult to pinpoint, it can be shown

that certain developments in science during the period between Vatican I and Vatican II, particularly relativity and quantum theory, and similar developments in Catholicism, particularly in scriptural scholarship and interpretation, missionary expansion, and wider interaction with other world religions and cultures, the fruitful involvement of many loyal Catholics like Georges Lemaitre in science, played a crucial role in this happy transformation.

The Chronology of the Different Events. On 25 January 1959, Pope John XXIII announced the convening of the Council. On 17 May 1959, the "Antepreparatory Commission" was appointed by the Pope. Ten preparatory commissions and 2 secretariats were established on 5 June 1960. The council commenced on 11 October 1962 under Pope John with 2450 members out of the possible 2908 and closed on 8 December 1965 under Pope Paul VI. The council had 4 principal sessions and produced 4 Constitutions, 9 Decrees, and 3 Declarations. In addition to these, there were also a number of "closing messages" to special target groups, introduced by the Pope and read out by cardinals appointed by the Council.

Special Features of the Council (1): Emphasis on the Pastoral Rather than Doctrinal Dimension. As the Apostolic Brief, given at the end of the council declaring its conclusion, pointed out, the council always bore in mind "the necessities of the present day, above all it sought to meet the pastoral needs." According to the "opening speech" of Pope John XXIII, the primary purpose of the council was not the discussion of any particular doctrine but to bring "the modern world into contact with the vivifying and perennial energies of the gospel, a world which exalts itself with its conquest in the technical and scientific fields, but which brings also the consequences of a temporal order which some have wished to recognize excluding God. This is why society is earmarked by a great material progress to which there is not a corresponding advance in the moral field." Thus, the council was intended to remedy the serious mismatch between the advances in the world of science and technology and in that of religion and morality.

Special Features of the Council (2): Greater Sensitivity to the Human Dimension. This council was particularly noted for its people-friendly vision and approach. It is remarkable that it began with a nontraditional opening "Message to Humanity," "to all men." Walter Abbott points out that this is the first time that a council addresses itself to all men, not just Catholics. In a personal note the Council Fathers assured all that they were in solidarity with the people, carrying in their hearts their "hardships, the bodily and mental distress, the sorrows, longings, and hopes." *Lumen gentium*, "Dogmatic Constitution of the Church," often considered "the most imposing achievement of Vatican II," described the same predicament of contemporary humans: Today, humans are "buffeted between hope and anxiety and pressing one another with questions about the present course of events, they are burdened down with uneasiness."

Special Features of the Council (3): The Spirit of "Aggiornamento." "Aggiornamento," making up-to-date, the catchword for the Council, expressed the goal that the Church must be brought up-to-date, must adapt itself to meet the challenges of modern times, particularly due to the astounding developments in science and technology. Pope John wanted the Church not to be intimidated by science but be daring to make use of modern ideas, means, and methods, well proven for their efficaciousness and accuracy, to expound and explicate the Christian teaching and heritage. Thus, the council would be "a step forward toward a doctrinal penetration and a formation of consciousness in faithful and perfect conformity."

Aggiornamento in the theological context should not be reduced to an exercise of rephrasing conventional theological teaching in contemporary terminology. The council clearly stated that such "old wine in new skins" simply defeated the purpose because scientific findings had posed new questions demanding new theological investigations.

Special Features of the Council (4): A Balanced Approach. At the same time, it must be emphasized that this aggiornamento in no way meant any break with the fundamental teachings

of the Church. To dispel any doubt on this matter, Pope John clarified: “The substance of the ancient doctrine of the deposit of faith is one thing, and the way in which it is presented is another. And it is the latter that must be taken into great consideration with patience if necessary, everything being measured in the forms and proportions of a Magisterium which is predominantly pastoral in character.” In fact, he most sincerely hoped that “illuminated by the light of this Council, the Church . . . will become greater in spiritual riches and . . . make men, families and peoples really turn their minds to heavenly things.” Clearly, one of the goals of this council was to help contemporary humans living in a world dominated by science and technology to achieve a delicate balance between the scientific and the religious, the material and the spiritual.

Special Features of the Council (5): A Positive and Non-Defensive Attitude. It could be said that Vatican II ushered in a new age in the life and attitude of the Catholic Church. In place of the spirit of “anathema sit” and condemnation prevailed that of understanding and compassion, meeting “the needs of the present day by demonstrating the validity of her teaching rather than by condemnation.” The request of many Council Fathers to reconsider the Galileo case and Pope John Paul II’s follow-up on the matter were an unmistakable testimony of this spirit. Another instance of this new spirit was the public expression of regret by Pope Paul VI and Athenagoras I, the Patriarch of Constantinople, on 7 December 1965 for the mutual excommunications pronounced by their respective predecessors Pope Leo IX and Patriarch Cerularius in 1054.

Special Features of the Council (6): The Spirit of Openness and Optimism. A spirit of optimism and positiveness that readily appreciated the good in other religions and systems and a spirit of openness to new possibilities, even when they looked challenging and demanding, was another hallmark of the Council. As Pope John said: “We feel we must disagree with those prophets of gloom, who are always forecasting disaster, as though the end of the world were at hand. . . . Everything, even human differences, leads to the greater good of the Church.” A similar

sentiment was expressed by Pope Paul VI: “From the start the Council has propagated a wave of serenity and of optimism . . . free of medieval rigorous and pessimistic understanding of man and his customs.” This openness and optimism was very conspicuous in the welcoming attitude the council took toward developments in science and technology, without losing its rootedness in tradition.

Special Features of the Council (7): The Spirit of Partnership and Collaboration. It is remarkable to note that the council expressed a very close and intimate relationship with the scientific community, as was articulated in the “closing message” of the Council. According to it, since scientists and the Council Fathers were fellow-seekers of truth, their paths “could not fail to cross. Your paths are never foreign to ours.” In fact, the relationship between the two groups was one of intimate partnership and close collaboration, as expressed in the following words: “We are friends of your vocation as searchers, companions in your fatigues, admirers of your successes and, if necessary, consolers in your discouragement and your failures.” The Council ardently encouraged them to continue the search “without tiring and without ever despairing of the truth.”

The Main Ideas of the Council

Importance of Science in Contemporary Society. The council correctly emphasized the fact that in the contemporary world science was fast becoming the foundation of intellectual formation. *Lumen gentium* says: “Intellectual formation is ever increasingly based on the mathematical and natural sciences and on those dealing with man himself, while in the practical order the technology which stems from these sciences takes on mounting precedence.” Furthermore, “Technology is transforming the face of the earth, and is already trying to master outer space.” The advances in the biological and social sciences too are equally powerful and effective: “Advances in biology, psychology, and the social sciences not only bring men hope of improved self-knowledge. In conjunction with technical methods, they are also helping men to exert direct

influence on the life of social groups.” In short, in our contemporary world, intellectual formation is very much colored and controlled by science and technology. The council was in praise of the methodology of science also. “If methodical investigation within every branch of learning is carried out in a genuinely scientific manner and in accordance with moral norms, it never truly conflicts with faith. For earthly matters and the concerns of faith derive from the same God.” It also affirmed “the legitimate autonomy of human culture and especially of the sciences.”

Genuine Appreciation of the Achievements of Science. According to Vatican II, far from being the devious devices of the devil, science and technology are a boon to humanity, ordained by divine dispensation. “By divine favour, especially in modern times, human genius has produced from natural material astonishing inventions in the field of technology.” The Church gladly welcomes them: “As a Mother, the Church welcomes and watches such inventions with special concern.... Mother Church, to be sure, recognizes that if these instruments are rightly used they bring solid nourishment to the human race.”

Science as an Affirmation of Human Dignity – Human Partnership in Creation. In a way, science is a powerful affirmation of human dignity and greatness and provides humans with a most effective means to collaborate with the Creator in the ongoing plan of creation. “When with the aid of technology man develops the earth ... he simultaneously obeys the great Christian commandment that he place himself at the service of his brother men.” A prudential, judicious engagement in science can elevate humans to a higher and more sublime level of moral and intellectual life. “Furthermore, when a man applies himself to the various disciplines ... of mathematical and natural science, he can do very much to elevate the human family to a more sublime understanding of truth, goodness, and beauty, and to the formation of judgments which embody universal values.”

Science Education for Priests and Other Leaders. The council emphasizes the need for

science education both for Church leaders like priests and the laity. This point is emphasized in the “Decree on Priestly Formation” and in the “Declaration on Christian Education.” In institutions of higher learning, the Church wants “in a systematic way to have individual branches of knowledge studied according to their own proper principles and methods, and with due freedom of scientific investigation.” According to it, “Catholic colleges and universities and their faculties should give the maximum support to institutes which primarily serve the progress of scientific research.”

The Impact of Science on Theology. According to the Council, theology is an important beneficiary of these scientific developments because they can “stimulate the mind to a more accurate and penetrating grasp of the faith. For recent studies and findings of science, history, and philosophy raise new questions which influence life and demand new theological investigations.” Hence, the council urges theology to be in constant touch with developments in the sciences, “through a sharing of resources and points of view,” collaborating “with men well versed in the other sciences,” and seeking “a profound understanding of revealed truth without neglecting close contact with its own times.”

Science at the Service of the Church’s Pastoral Mission. The council readily acknowledges and appreciates the positive values accruing from the scientific spirit such as fidelity to truth, team spirit, etc., Science and its findings can be equally beneficial in the area of pastoral care. The council reminds pastors and other ministers to make use “in pastoral care ... the findings of the secular sciences, especially of psychology and sociology.” In fact, it wants the faithful to “blend modern science and its theories with Christian morality and doctrine. Thus their religious practice and morality can keep pace with their scientific knowledge and with an ever-advancing technology.”

Openness to the Dynamic Worldview of Science. Vatican II in some ways shows an openness to the scientific dynamic worldview in which change is an essential part, particularly in

Gaudium et spes, “Pastoral Constitution on the Church in the Modern World of Today,” where it says: “The human race has passed from a rather static concept of reality to a more dynamic, evolutionary one.” The consequences of this paradigm shift are enormous, and the Council, well aware of this fact, observes: “In consequence, there has arisen a new series of problems, a series as important as can be, calling for new efforts of analysis and synthesis.” This sensitivity to the dynamic worldview of modern science and this openness to its consequences played a crucial role in defining the Council’s attitude to science and technology. They can play a pivotal role in fostering a constructive and creative dialogue between Christianity and modern science.

Holistic Approach Toward the Divine and the Human. Vatican II encourages a holistic approach to the divine and the human, the supernatural and the natural. It looks for “a spiritual renewal from which will also flow a happy impulse on behalf of human values such as scientific discoveries, technological advances, and a wider diffusion of knowledge,” indicating a close link between spiritual renewal and scientific activities, an idea reminiscent of the thought of Teilhard de Chardin. A very positive attitude toward the world that was created by God who “found it good” can never be alien to the Church of God.

No Excessive Importance of Science. As Pope John made very clear, the Church has been a vigilant and alert observer of scientific developments, following “step by step the evolution of peoples, scientific progress, and social evolution.” At the same time, it “does not neglect to admonish men so that, over and above sense – perceived things – they may raise their eyes to God.” It has taken pains to distinguish between “excesses associated with a spirit of scientism and the permanently valid achievements of the positive sciences over the past few centuries.” While recognizing the legitimate independence of the world of science, it always rejects the false sense of independence, which is taken to mean that “created things do not depend on God, and that man can use them without any reference to their God.”

Conclusion

Our brief survey reveals considerable difference between Vatican I and Vatican II in many respects. Perhaps one of the main reasons for this marked difference was the attitude each had toward science. For Vatican I, science was a contender to be tackled firmly and decisively. For Vatican II, science is a partner with whom the Church needs to collaborate in an ongoing search for truth. It seems clear that this spirit will continue as Pope John Paul wrote to Fr. George Coyne, SJ, in 1988, the then Director of Vatican Observatory: “The truth of the matter is that the Church and the scientific community will inevitably interact; their options do not include isolation.”

Description

A Catholic sociology is a subdiscipline within the broader discipline of sociology. It builds on generally agreed upon insights about the role of basic sociological considerations in an analysis of social life (e.g., culture, socialization, groups, social stratification, etc.). It also follows the generally accepted canons of social science research in terms of issues, such as method, evidence, and reasoning. Catholic sociology is sociology that takes the sociological enterprise seriously, is consciously upfront and explicit about its fundamental assumptions, and aims to contribute to its positive development by enriching the internal intellectual exchanges within the general discipline.

At the same time, a Catholic sociology attempts selectively to incorporate elements of

Catholic theological and philosophical analysis into both the “front” and “back” ends of its overall analysis, that is, respectively, into its theoretical framework and into a range of possible social policy suggestions that are consistent with its cognitive analysis of social life. A Catholic sociology argues both the inevitability and desirability vis-à-vis, respectively, theory and public policy, of incorporating elements of, and concepts from, normative analysis, especially as derived from the Catholic social doctrine, Catholic social thought, and “natural law” analysis. It does so without compromising its cognitive function and mission of arriving at a truthful and objective depiction of social reality. Examples of such incorporated elements and concepts would be the fundamental dignity of the human being made in the image of God; the individual viewed ultimately as a spiritual being with a soul and eternal destiny; the individual characterized as possessing free will and viewed as a responsible social agent with both duties and rights; a concern for the common good; subsidiarity; solidarity; the family as the basic cell of civilization; and the compatibility and complementary nature of faith and reason. Such an interdependent, three-tiered conception of a Catholic sociology has developed slowly, in fits and spurts, over the past century and a half. This is the result of two processes. The first is an increasing awareness that there are limits to the useful employment of specialization in research. The second is an increasing awareness of intellectual freedom to socially construct and modify intellectual perspectives encouraged in the current “post-modern” culture.

A Catholic sociology is consistent with the argument of the Protestant scholar, George Marsden (*The Outrageous Idea of Christian Scholarship*), that Christian ideas can and should be incorporated into academia in a way that does not violate reasonable, tradition-tested, and widely accepted philosophical and methodological conventions. For Marsden, whether religious or secular in nature, worldviews “help shape not only our overt ways of valuing things, but also our priorities. What do we see as important to study? What is it about that subject which makes it interesting? What are the questions we ask that

will organize our interpretations of this topic? What theories do we entertain as relevant to our interpretations? What theories do we rule out?" (1997: 63). The Catholic sociologist Joseph A. Varacalli similarly offers a fivefold classificatory scheme of the impact of values on the social scientific enterprise involving (1) *motivation*, or in some cases, *ideological agenda*; (2) *choice of research project or social problem*; (3) *selection of data as relevant* or, conversely, aspects of social reality ignored; (4) *interpretation of data, involving analytical concepts, definitions, and theoretical frameworks employed*; and (5) *possible social policy recommendations* (Varacalli 2000: 7–8).

Both the formulations of Marsden and Varacalli are consistent with the claim that, while any investigation takes place within a given frame, there is a responsibility to dialogue with other frames as well as search out and document whatever is perennial in social life. The sentiments of Marsden and Varacalli are consistent with that of Ralph Gallagher, the first president of the American Catholic Sociological Society (founded in 1938), who declared that "there *is* such a thing as a Catholic sociology, for sociology is not, in the full sense of the word, an exact science. The method of investigation, the assembling of data, the conclusions drawn depend frequently upon the thought and philosophy of the investigator." Gallagher quickly added, however, that "...certainly we can learn much from those whose approach is different from ours. They have much to contribute in the field of method and research. We have no intention of becoming advocates of intellectual isolation" (quoted in Varacalli 1990: 249). Following the general direction of the Catholic sociologist of knowledge, Werner Stark (*The Sociology of Knowledge*), a premise of a Catholic sociology is that the pursuit of truth must work its way *through* culture and society, accepting and emphasizing those conceptual elements and visions of humanity that can justifiably lay claim to a perennial status, thus separating itself from the contingent and utopian. Stark argues that, through a careful analysis of sociohistorical reality, "the absolute is

recognizable...in, through, and under the relative... 'to the absolute through the relative is our device'" (1958: 196).

One characteristic of a Catholic sociology is a "moderate integration" between the metaphysical, empirical, and social reform realms of analysis. This characteristic generally separates a Catholic sociology from more conventional understandings of the discipline, the latter which tend not to address its own metaphysical presuppositions. A Catholic sociology, as such, rejects the argument of Max Weber about the possibility of "value-free" sociology.

A Catholic sociology would respond to those who advocate Weber's view that, to the contrary, the mutually agreed upon goal of objectivity in social research requires two procedures. The first is the introduction of a theoretical/conceptual framework derived from, or consistent with, the natural law and Catholic social doctrine and thought. The second, methodologically, is the conscious juxtaposition of competing frameworks, pace Karl Mannheim (*Ideology and Utopia*), as an aid in reaching a truthful and comprehensive analysis of issues of major ethical import.

In his *Ideology and Utopia*, Mannheim proposed that a "socially unattached intelligentsia" could approximate objectivity in analysis by comparing competing existentially based social and historical perspectives in the attempt to weed out ideological distortion and structurally based biases. Many scholars, including non-Catholics, have concluded that Mannheim's methodology, while broadening academic discourse, has not provided, in and by itself, an escape route from error and a path toward truth. For the Catholic sociologist, any path toward truth additionally must acknowledge some metaphysically based natural law-like analysis or a phenomenological analysis connecting an absolute realm of eternal values with the relativities involved in empirical analysis (Varacalli 2012: 103).

Following the logic of Jacques Maritain in *The Peasant of the Garonne*, the metaphysical, empirical, and social reform levels of analysis in Catholic sociological research are interdependent and mutually shaping. For Maritain, "between

faith and reason, as between grace and nature, there is essential distinction and one sometimes tends to lose sight of it. . . But between faith and reason, as between grace and nature, there is no separation. One tends to overlook that too. . . Things are that way, and so is life; there is distinction without separation" (1968: 166–167).

That there can and should be a moderate integration between the metaphysical, empirical, and social policy levels of analysis points to the assertion of a Catholic sociology that the general discipline of sociology is itself not fully self-contained but only semi-autonomous and interdependent. Just *why* the broader discipline of sociology has posited a rigid segregation between fields of knowledge is an important question that involves many partial answers. Among others, these involve an overreliance on the positivistic scholarly tradition; the perceived need to defend the integrity of sociology vis-à-vis religion, philosophy, and the humanities; and the desire of sociologists to capitalize on the status and material benefits that accompany the "scientific" label.

There is no doubt that, with few exceptions, there is vigorous opposition on the part of the mainstream sociological establishment to any sociological connection with a metaphysical realm. As one of the most accomplished and respected sociologists in the history of the discipline, Robert Merton, puts it in his critique of the work of Max Scheler, any discussion of "absolutes" is "wholly foreign to empirical inquiry" (1957: 472). The response of a Catholic sociologist to this claim is that *all* sociologies are tied to what the sociologist Alvin Gouldner (*Enter Plato*) termed basic, foundational, or "domain" assumptions about the nature of reality, society, and human beings. These domain assumptions can be found (to whatever degree, either explicitly or implicitly) in the Calvinism in the work of Talcott Parsons and Robert N. Bellah, the Marxism in the work of C. Wright Mills, the Lutheran heritage in the work of Peter L. Berger, the portrayal of the radically "protean" or "plastic" nature of the human being in the work of the symbolic interactionist Herbert Blumer or the dramaturgical approach of Erving Goffman, in

the atheistic existentialism in Stanford Lyman's and Marvin Scott's "sociology of the absurd," in the behaviorist assumptions underlying a rigorist mathematical sociology, and so forth.

The Catholic sociological call for a "moderate integration" does not deny, conversely, the necessity, inevitability, and desirability of some significant degree of disentanglement of social science from, first, theology; second, philosophy; and, third, social policy. What the former *does* argue is that specialization has proceeded too far, producing sub-universes of meaning that are compartmentalized and mask inevitable interdependencies, thus doing an injustice to the intellectual requirement to produce comprehensive and holistic analyses of life that nonetheless are capable of making and acknowledging subtle and necessary distinctions between faith and reason and metaphysics and empirical reality. Max Scheler's critique, in his *Problems of a Sociology of Knowledge*, of Auguste Comte's zero-sum evolutionary movement from *myth* to *philosophy* to *science* (or a positivistic social science) is quite consistent with the Catholic position regarding the relationship, over time, of those social constructions based on the absolute to those that more reflect a relative cultural ethos. For Scheler (1980), the absolute is ever present throughout time and space in the form of an eternally valid hierarchy of values although any specific cultural ethos may distort the true ordering of these values. When this happens, for Scheler (1980: 13–23), various "disorders of the heart" are produced, that is, pathologies at the level of both society and the individual.

The Catholic appropriation of sociology sets itself up in sharp relief from either of the two current and major alternatives in the field, that is, the *ideological* and *positivistic* models as discussed by the sociologist Peter L. Berger (2011). The ideological perspective, which gained political dominance in the mid-1960s in the contemporary academy, assumes two things. The first is that the political cause of choice is more important than the integrity of the scholarly process. The second is that the reality that the philosophy and personal values of the researcher affects the nature of the research process makes

the goal of objectivity an impossible one, representing nothing more than a clever rationalization and intellectual tool used by the guardians of the political *status quo*. The positivistic model, while arguing for objectivity, tends to view the individual and the individual scholar as devoid of free will, creativity, and responsibility. Generally, it has fallen into the trap of a methodological fetishism encouraged by a hyper-specialization focusing on topics of little or no importance to those concerned with the construction of a “good society.” The goal of a “Catholic sociology,” in contrast, is to analyze and reconstruct the social order on the basis of sound/right reason and empirical evidence. What makes it a “Catholic” sociology is the application, when appropriate, of insights and sensibilities developed within the corpus of Catholic social theory to the existing body of sound social scientific theory, concepts, and methods, and through a thorough public exchange (Varacalli 2000: 6–11).

There are multiple (empirically existing and theoretically possible) versions of a “Catholic sociology.” This complexity results from considerations involving intellectual pluralism and prudential application. Regarding intellectual pluralism, the individual Catholic sociologist can make recourse to a variety of theological and philosophical schools of thought, assuming that the latter can be plausibly judged as existing within the broad parameters of a Catholic worldview. Another consideration is that the discipline of sociology itself contains many – and in certain cases, seemingly disparate – theories and schools of thought. While none of the major options within the broader sociological tradition are, in and by themselves, consistent with a Catholic logic, some can claim a closer affinity to Catholic thought than others. For instance, and although differing from each other in significant ways, the “structural-functionalism” of Talcott Parsons with its organic understanding of social institutional arrangements and its discussion of a “telic” system, and the “integral” sociology of the Russian Orthodox sociologist, Pitirim A. Sorokin, with its linking of the empirical, rational, and other-worldly transcendent realms of analysis,

bears certain affinities with the thought of St. Thomas Aquinas. Likewise, the “debunking” sociology of the liberal Lutheran sociologist, Peter L. Berger, shares some affinity with the thought of St. Augustine. Other sociologies are harder to reconcile, if the Catholic sociologist affirms the parameters of acceptability as outlined by the magisterium (or teaching authority) of the Catholic Church. Regarding the issue of prudential application, there can be a broad array (albeit not of an indiscriminate nature) of possible social policy recommendations that flow from the cognitive analysis of a Catholic sociology. In other words, there are various licit and legitimately debatable means toward instituting the common good.

This brings up the reality that there are both “official” and “unofficial” versions of a Catholic sociology. The former accepts the parameters of the Church’s teaching authority (or *magisterium*) as the field from which its intellectual and normative formulations are chosen. The latter refuses to do so, arguing, pace the logic of “Christ of culture” thinkers like Harvey Cox (*The Secular City*), that any social construction can be consistent with a Catholicism undergoing constant, even radical, and officially unsupervised change. In his *A Theology of Liberation*, for instance, Gustavo Gutierrez, offered a “Marxist-Catholic” synthesis widely viewed by orthodox Catholic scholars as reducing the Catholic faith to Marxist categories of thought along the lines of the general methodological critique offered in two statements issued by the Congregation for the Propagation of the Faith whose prefect was the then Cardinal Joseph Ratzinger. These statements are the 1984 *Instruction on Certain Aspects of the ‘Theology of Liberation’* and the 1986 *Instruction on Christian Freedom and Liberation*. Also relevant is the document published by the Congregation for Catholic Education in 1989, that is, *Guidelines for the Study and Teaching of the Church’s Social Doctrine in the Formation of Priests*. There are currently a plethora of unofficial (and mostly implicit) Catholic sociologies accepting concepts and theories (e.g., “androgyny” for radical feminists and “queer theory” for homosexual activists) which

advocate positions fundamentally at odds with an official Catholic understanding of human nature and the overall magisterial worldview. Many, although not all, of these nonmagisterial understandings derive from a radical, “post-modern” interpretation of “social constructionism” for both the discipline of sociology and for the broader civilization; others derive from the acceptance of various visions of life based on “modern” philosophies whose root assumptions are incompatible with a Catholic vision (e.g., Communism, Freudianism, *laissez faire* Capitalism).

It should be stated immediately that the role of the Magisterium vis-à-vis a Catholic sociology is subtle. Positively viewed, it is a source of inspiration regarding insights about human and social existence. It does not enter, as a matter of everyday routine, into specific sociological debates. Periodically, it produces statements when schools of thought or individual scholars explicitly negate fundamental assumptions about the existence of God, the nature of society, the individual, and their relationships.

The origins of the idea of a Catholic sociology arose concomitant with the development of the general discipline. It developed “negatively,” that is, in reaction to the non-Catholic elements influencing the emergence of the discipline (whether inspired by Auguste Comte, Herbert Spencer, Karl Marx, Emile Durkheim, or liberal Protestant thinkers). The idea also developed “positively,” that is, originally in “proto”-Catholic sociological form, in response to the developing tradition of social Catholicism (Williams 1950). The social apostolates promoted by, for instance, Bishop William Emmanuel von Ketteler (1811–1877) in Germany and Edward Henry Cardinal Manning (1808–1892) in England both influenced the content of the social encyclical, *Rerum Novarum*, in 1891 and contained implicit sociological analyses of civilization.

In Europe, sociology as a general intellectual perspective developed as a response to the forces of exaggerated social change that tended to undermine what the social philosopher, Alfred Schutz, termed the “taken-for-granted”

assumptions of social life, especially from the nineteenth century forward. These social forces included ideas derived from the eighteenth century Age of the Enlightenment and the rise of science, structural developments like industrialization and urbanization, and historical events like the American and French Revolutions and *Il Risorgimento* in Italy. The resulting volcanic changes produced a general divide between those ascendant sectors strongly progressive and secular and those defending tradition, the *status quo*, and tied to the aristocracy and a defense of its rigid system of social stratification. For most of the European founders, the various sociological formulations were viewed as enlightened substitutes for religion, whose function was not merely cognitive but served as functional replacements and equivalents for religion. This cultural, religious, social, and academic divide placed those advocating a reconciliation between Catholicism and the newly emerging and “modern” discipline of sociology in a “no man’s land.” Relevant here are the stages of history as discussed by the Catholic historian/sociologist, Christopher Dawson. As Edward King notes, “Dawson characterized his sixth and final historical era as that of ‘secularized Christendom and the Age of Revolution’ which spanned from the eighteenth century to the present... (This)... is Christendom with a profound spiritual vacuum at its core, and its history over three centuries shows the rise of a series of secular prophets who sought to fill this vacuum” (2007: 280).

Nonetheless, there were individual attempts to make such a negotiation between Catholicism and sociology. Increasingly more articulate Catholic sociological formulations were created by such figures as Christopher Dawson (1889–1970) in England (and later the United States), Frederic LePlay (1806–1882) in France, Cardinal Joseph Hoffner (1906–1987) in Germany, and Don Luigi Sturzo (1871–1959) in Italy. These individual scholarly attempts were part of the same social matrix which saw the emergence of Catholic social doctrine in the form of such encyclicals as *Rerum Novarum* (1891) and *Quadragesimo Anno* (1931). These attempts tried to address the needs of the “social

question” for the majority mired at the societal periphery and to provide a Catholic critique and alternative to such secular ideologies as capitalism, socialism, and Communism.

In the American context, the proto-Catholic sociologists fought their own two-front war. The first front opposed the liberal Protestant Social Gospel movement dominant at the turn into the twentieth century which focused on establishing “God’s Kingdom here on earth.” After the carnage of World War I, the second front opposed the newly emerging heirs to Auguste Comte, in the form of such positivistic sociologists like William Ogburn (1886–1959) and George Lundberg (1895–1966). Some key early founders of a Catholic sociology/social science in the United States were William J. Kirby (1870–1936), Monsignor Paul Hanly Furfey (1896–1992), and Eva J. Ross (1903–1969).

The attempt from 1938 to 1970 to institutionalize Catholic sociology in the United States through the American Catholic Sociological Society failed primarily because of several inter-related reasons. One was a lack of institutional support from an institutional Church where the majority of its scholars felt secure that truth could be approached almost exclusively through the deductive disciplines of theology and philosophy. Another was the still working-class backgrounds of most Catholics, a reality not amenable to a wide-scale acceptance of the utility of social science perspectives. Another was the desire of young Catholic sociologists and social scientists trained in secular universities to conform to the standards of the mainstream and secular profession.

Regarding the latter reason, the secularization that overtook the A.C.S.S. and many other Catholic scholarly organizations in the post-Vatican II period involved an interpretation of the significance of the theology of Vatican II (1962–1966) for Catholic scholarship that argued, basically, that the state of existing Catholic scholarship was inferior to the secular scholarship of the time. An important argument laying the groundwork for this line of thinking was the essay of the influential, progressive American Catholic historian, Monsignor John

Tracy Ellis, *American Catholics and the Intellectual Life* published in 1956.

Advocates of a Catholic sociology made the contrary claim that the Council actually affirmed the need for Catholics to engage in public dialogue about what their religion – with its intellectual heritage – had to offer to both the world and sociology. In their view, the Council was incorrectly interpreted as signaling the obsolescence of the ideal of distinctive Catholic intellectual approaches (Varacalli 1990: 250–251). As such, the transformation of the American Catholic Sociological Society into the Sociology of Religion in 1970 was viewed an indicator of the power of assimilation into the mainstream conventions of the secular discipline of sociology, with more than a few of these conventions subject to legitimate criticism from a Catholic intellectual perspective.

However, that same secularization was also an indicator of the weak tradition of, general lack of competency in, and lack of enthusiasm for, the social science enterprise on the part of the Catholic Church and Catholics in general vis-à-vis the more completely secularized and progressive camps within the overall discipline of sociology. For decades after the conclusion of the Second Vatican Council, either an overt secularization or a more subtle “secularization from within,” continued to erode any effective interface between Catholicism and sociology, thus attenuating, to the point of utter dormancy, the reality of an official Catholic sociology. This secularizing movement was carried, variously, by the general processes of assimilation into an increasingly less religious society and specifically fomented by Catholic progressive elites.

This trend has now started to be reversed, in part, a consequence of Pope John Paul II’s “new evangelization.” Also, the importance of social science research has increasingly been accepted, in a “taken-for-granted” fashion, by most of the increasing percentage of formally educated Catholics in the contemporary world. As but one indicator of this, the Society of Catholic Social Scientists was formed in 1992, convening annual national conferences; publishing a journal, the *Catholic Social Science Review*;

and instituting a book series on the themes of Catholic social thought and the connection between Catholicism and the social science disciplines. Most relevant to the discussion of a Catholic sociology is the substantial volume put together and edited by Stephen R. Sharkey, *Sociology and Catholic Social Teaching: Contemporary Theory and Research* (2012). Sharkey provides a range of contemporary social scientists from both the S.C.S.S. and the Pontifical Academy of Social Sciences who use their theoretical and empirical work to serve both the Church and the broader civilization. In his discussion, he also notes other contemporary schools of thought that can serve to foster a vivifying exchange between religion and sociology (e.g., “personalist critical realism” and “integral sociology,” the latter based on the work of Pitirim Sorokin).

While the S.C.S.S. has made substantial internal progress over its first 20 years, its ultimate fate is tied to such issues as the general reception of the idea of specifically Catholic perspectives in scholarship among its membership, the state of Catholicism within the broader American and world civilization, as well as the direction of the internal currents of the sociological profession. Regarding the latter, Sharkey suggests that the prospects of a Catholic sociology are superior in the present post-modern society for two interrelated and overlapping reasons. The first is that post-modern society is characterized by a greater self-reflexivity vis-à-vis the immediately preceding post-traditional, “modern” era. The second is the growing rejection both of positivistic notions of a “value-free” sociology and overt ideological scholarship.

Self-Identification

Science

A “Catholic sociology” is a subdiscipline of sociology which itself is an example of a social science. Social science perspectives can lean in either the scientific or humanistic direction. Without violating the scholarly canons for

empirical research, a Catholic sociology definitely leans in the humanistic direction emerging, in part, because of its rejection of the inadequacies of the pseudo-scientism of positivism.

Religion

An “official” Catholic sociology is *not* defined as a “religion.” A semi-autonomous Catholic sociology is viewed by its advocates as a licit *means* to actualizing one’s primary religious, intellectual, and moral commitments to a Catholic worldview. However, an “unofficial” Catholic sociology could be defined as a religion, following what sociologists refer to as a “functional definition” of religion. So defined, an unofficial Catholic sociology combines a scholarly analysis of Catholicism and religion with either an ultimate interest in promoting autonomy in intellectual, religious, and moral affairs or in some other essentially secular philosophy/worldview.

Characteristics

A Catholic sociology draws on the distinctive insights of human personhood and sociability inhering in the Catholic intellectual tradition. Catholic sociology as a subdiscipline is distinctive in at least several ways. One is the Catholic conviction that faith and reason are compatible and mutually supportive. Another is in the attempt to systematically relate and demonstrate interdependencies between normative and cognitive analyses, between, more specifically, the realms of metaphysics, empirical research, and social policy. Yet another is its attempt to reintegrate knowledge and produce holistic knowledge in order to provide analyses of social existence that are comprehensive, subtle, and complex.

Relevance to Science and Religion

A Catholic sociology is certainly interested in and can contribute to the scholarly area called “Science and Religion.” A Catholic sociology accepts the idea that the discipline of sociology

has inclusive tendencies, that is, that it can and should incorporate the insights of interdisciplinary research. A Catholic sociology also views the scientific enterprise as not fully autonomous, that is, that scientific activity, while maintaining a legitimate semi-autonomous status that resists any facile reduction to nonscientific considerations, is both affected by cultural and social factors and has tremendous consequences for the civilization in which it operates. The actual and potential implications of current biotechnological revolution for civilization highlight the latter claim.

Sources of Authority

There are dual sources of authority for the idea of a Catholic sociology. The first source comes from the secular mainstream tradition of the discipline of sociology in the form of what has been termed “basic sociology,” (James M. Henslin, *Essentials of Sociology: A Down to Earth Approach*, Ninth Edition). This tradition stresses certain fundamental postulates. One would be an emphasis, relative to most philosophical and theological thought, on empirical reality. Another would be the goal of objectivity. Another involves the requirement that all aspects of the research process be open for review and accountability and be conducted under ethical guidelines.

The second source of authority for the subdiscipline is found within the corpus of Catholic social thought. Given the present influence of both positivistic and ideological thinking, Catholic sources of authority for this subdiscipline are not widely recognized outside the sphere of “official” Catholic thinking or that relatively small segment of religious thinkers who utilize the sociological discipline in their various religious, intellectual, and policy “apostolates” and “ministries.”

The establishment of a “Catholic social science” was first called for in official Catholic circles by Pope Pius XI in his important encyclical, *Quadragesimo Anno*, #20, (1931). This important social encyclical was produced

40 years after the publication of what is generally acknowledged as the first great social encyclical, *Rerum Novarum*, issued by Pope Leo XIII in 1891 as a response to the conditions of the working classes as the dysfunctions of the industrial revolution in Europe became manifest. Building on more than 100 years of development within the corpus of Catholic social thought since the publication of *Rerum Novarum*, Pope John Paul II established the Pontifical Academy of Social Sciences in Rome in 1994. According to the Vatican web site, the Pontifical Academy of Social Sciences was founded “with the aim of promoting the study and progress of the social sciences, primarily economics, sociology, law, and political science, thus offering the Church those elements which she can use in the development of her social doctrine, and... (in)... reflecting on the application of that doctrine in contemporary society.” While the Pontifical Academy has not addressed yet the specific issue of to what degree and in what ways the social sciences can be “Catholicized,” the idea that objective social science can contribute to Catholic social thought and the broader civilization represents some initial positive movement in the direction of a fruitful exchange between Catholic social thought and the mainstream tradition of the discipline.

As of now, however, a deliberate Catholic sociology exists in more or less restricted circles. Mention should also be made regarding the debatable issue of the degree to which the principles of a Catholic sociology (e.g., a positive role for values in the research process, a concern for human dignity and social justice – as understood in official Catholic sources – have started to become institutionalized in Catholic colleges and universities).

The widespread “plausibility” of a “Catholic sociology” depends on two related issues. The first is the possibility of a revitalization of Catholicism/Christianity in world civilization and within the secular academy. The second, conversely, involves the issue of whether the concurrent debunking of the monopolistic status and claims of both positivism and of ideological

thinking within secular academic circles will continue into the future. There are two questions here. The first is whether the Catholic intellectual community has the will and ability to develop more fully a Catholic sociology. The second is whether there might be a change in attitude in social science circles regarding the idea that the cognitive and normative claims of traditional religion can contribute in a positive manner to intellectual discourse.

Ethical Principles

There are several distinctive overriding ethical principles which inform Catholic sociology as reflected in the Catholic intellectual tradition and especially within the social encyclicals. The first is to pursue truth, wherever that truth may lead. A second and third is that the subdiscipline serves the interests of the common good and the fundamental dignity of the individual, in terms of the latter's integral human needs, both spiritual and material.

Key Values

There are several key values for the subdiscipline of a "Catholic sociology." One is that human beings are constitutively "cultural and spiritual creatures," however modified by an awareness that cultural and spiritual realities are mediated and affected by (but not reduced to) material states of being, historical and personal realities and exigencies, and by a human nature that, while variegated in its manifold expressions, is essentially common and unchanging. Another is that human beings are not merely products of their "social location." The power of the human mind to reflect on the nature, causes, and impact of socialization create the grounds for the assignment of responsibility for human thinking and action, however mitigated by such factors as the nature of one's inherited and present social environment, stage of human development, and state of mental health. Another key value is the

positing of the inevitable interaction of a metaphysical realm with both society and sociology in the form of the natural law or its equivalent that helps provide a yardstick in social analysis allowing one to partially transcend the empirical reality of relativism. Another value is the positing of the existence of a supernatural realm which rejects the idea that all phenomena in social life can be completely and neatly explained. Both the nature of the individual – marked by an essential freedom and some degree of unpredictability – and his/her orientation to the transcendent realm presuppose that some of social life remains "mysterious." From a Catholic sociological perspective, put another way, no finite human agency has the ability to understand all of reality in its fullness and complexity. Finally, one of the constitutive goals of a Catholic sociology, given its positing of the ultimate other-worldly destiny of human beings, is as an aid to the individual in reaching the beatific vision.

Conceptualization

In addressing the following issues, it is important to preface the respective discussions by noting that a Catholic sociology affirms the religious/transcendent realm, especially as it conceptualized within the Catholic tradition.

Nature/World

The essence or substance of the created universe, including both the supernatural and the social universe, knowledge of which can be studied objectively through the use of the natural, social, and theological intellectual disciplines. From a Catholic sociological perspective, any understanding of earthly life, with its promotion of the essential dignity of the human being, must be integrated into a larger transcendent vision which understands that the ultimate origins of life come from God and that the ultimate destiny of the human being is the beatific vision. It is the social universe as it intersects with the natural and transcendent realms that is the special purview of a Catholic sociology as discussed by,

among others, the early Catholic sociologist, Don Luigi Sturzo.

Human Being

The individual, possessing both a body and soul, and capable of rational thought, voluntary action, and reaching truth, whose rights and duties derive from God through the natural law. Constitutive components of the human being as depicted by a Catholic sociology include a foundational spiritual and cultural dimension as well as the operation of the “natural law” written into the heart.

Life and Death

Viewed in terms of the earthly existence of the human being, activity which begins at the moment of conception and terminates with earthly death. Theologically, the soul continues in the next life within the spheres of Heaven, Hell, or temporarily, Purgatory. A Catholic sociology, in its social policy aspects, is committed to protecting and promoting the fundamental dignity all human life from the moment of conception through natural death.

Reality

All that exists objectively in the natural and social universe, that is, outside the mind of the individual. Regarding social existence, the dictum of the classical sociologist, Emile Durkheim, is relevant, that is, that “social facts are things.” One focus of a Catholic sociology is the determination of which social constructions are consistent with the natural law.

Knowledge

The cognitive understanding of God, the historical and social universe, the individual, and their relationships. Knowledge is acquired through reason and the senses but is aided and strengthened by revealed truth and the invisible operations of grace. A Catholic sociology takes from the sociology of knowledge the distinction between the “plausibility” and “truthfulness” of knowledge claims. Regarding the former, it accepts the dictum of the early “Chicago school” sociologist, W.I. Thomas, that “if something is

defined as real, it is real in its consequences.” However, following such scholars as Werner Stark and Max Scheler, it also considers one of its goals the pursuit of truth through a scholarly and discerning analysis of society, the human being, and the dialectical relationship between the two.

Truth

Objective factual/cognitive reality in the natural universe and objective factual/cognitive and moral/normative reality in the social universe, reached through the two complimentary wings of faith and reason. The desire to know the truth is intrinsic to the human being. A distinguishing characteristic of a Catholic sociology is the goal to identify truth and morality in society and social relations.

Perception

A way of understanding or interpreting. A Catholic sociology accepts, but only as a partial truth, that varying cognitive and normative understandings of reality inevitably are generated by the sociological reality of a differential socialization along a host of variables (e.g., cultural context, socioeconomic class, age, cohort, education, region, occupation, lifestyle, etc.). These cognitive and normative definitions are amenable, to a certain degree, to being documented through conventional sociological research. However, Catholic sociologists also affirm a deeper form of knowledge that comes not from purely empirical data gathering techniques but from the exercise of what the early Catholic sociologist, Monsignor Paul Hanly Furfey, referred to as “noesis” or the ability of the mind to immediately perceive certain truths or fundamental essences in the tradition of Plato and, derivatively, in the Catholic sociological work of scholars like Max Scheler and Werner Stark.

Time

The sum total of past, present, and future periods of existence. A Catholic sociology simultaneously takes into account different secular and religious conceptions of the temporal without violating the overall Catholic narrative on the

purpose of meaning of human existence. These include a straightforward understanding of chronological time; time understood as divided into cultural, political, and historical categories (e.g., the “Age of the Enlightenment”); time viewed from contrasting traditional and modern perspectives (e.g., the past as eternally present vs. a future open to human calculation and planning); and time viewed from a perspective centering on the creation of the universe by God, the historical reality and salvific mission of Jesus Christ, and the future anticipation of God’s plans for civilization and humanity.

Consciousness

A subjective and immediate awareness either of the external world and transcendent realm or of some intra-subjective mental state. Relatedly, individual consciousness/conscience may or may not be more or less in line with objective reality/truth/morality depending on a combination of circumstance, choice, and grace. One tenet of a Catholic sociology is that consciousness/conscience is in a dialectical relationship with the state of the surrounding civilization and one’s primary group attachments. One important Catholic sociological concern involves an analysis of modern consciousness and the question of its openness to the transcendent realm.

Rationality/Reason

A faculty of the human being to reach or at least approximate truth, despite the reality of original Sin and the inevitability of human error. Reason is meant to be assisted by Faith. Faith without reason produces a fideism which ignores/underplays the reasoning capability of the individual typical of formulations generated by advocates of the Protestant Reformation. Reason without faith produces a rationalism which overextends itself and lends itself to a destructive utopianism typical of advocates of revolutionary thought and action (e.g., French Revolution, Communist revolutions in Russia and, later, China, etc.). One important Catholic sociological concern involves an analysis of the dysfunctions associated with the increased growth of bureaucracies and

the bureaucratic mentality, supposedly based on rationality/reason, in the modern world.

Mystery

The theological, anthropological, and sociological reality that no purely human, finite agency can explain the fullness of the natural, social, and religious universe. The Catholic sociological acceptance of a significant role for mystery in social affairs lends itself strongly to the humanistic and “actionist” perspectives within the overall sociological tradition.

Relevant Themes

The utility and logic of the idea of a “Catholic sociology” depends on more than the exercise of reason and an examination of historical reality. Accepted here is the premise of the sociology of knowledge that ideas do not rise or fall (at least in the short run) on the issue of truth. Rather, all ideas, whether true/logical/useful (or not), depend on what sociologist Peter L. Berger has termed a “social base” or “plausibility structure” (*The Sacred Canopy*). The plausibility of an idea depends significantly on unpredictable future historical developments. It is scholarly paradigm (Thomas S. Kuhn, *The Structure of Scientific Revolutions*; Robert W. Friedrich, *A Sociology of Sociology*) awaiting its moment.

Religious Aspects of Causality

Ancient Judaism covers so many centuries that it is not surprising that it does not present a unified picture. The earliest of the literary prophets, such as Amos and Hosea (eighth century BCE), clearly believed that humans have free will, that their future is not predestined, but it is conditional depending on the behavior of the people. Predictions of doom and destruction are meant to instill ethical practices specifically to avert the dire predictions.

Deuteronomy (seventh century BCE) speaks clearly of a choice between following Torah (law) and disobeying it. A certain element of causality (but not predestination) is maintained. The correct choice leads to prosperity and happiness, but the wrong choice leads to ruin (Deuteronomy 30:15–20).

Although Jeremiah (early sixth century BCE) often sounds as though people have choice, he is much more predestinarian than his predecessors. Even his birth is seen as predestined by God, as is his calling as a prophet. Times were much worse; the political, military, and economic welfare of Judah had come close to destruction, and predestination seemed the only explanation: We do not

like it, but God's plan has something good as an outcome.

Prophets of the exile such as Ezekiel and Second Isaiah (Deutero-Isaiah, chs. 40–55 of canonical Isaiah) were preaching to a powerless people. They considered that only God's will and strength could restore the Jews to a measure of freedom and ability to practice their inherited religion. Predestination offered hope.

During the Persian, Greek, and Roman periods, a religious fragmentation of Jewish thought was in place. Pharisees, for example, believed in predestination; Sadducees opposed it. Early Christianity presented a mixture of ideas on the subject. Paul, a former Pharisee, taught predestination. The Gospels are not nearly so clear about it.

Ancient Greek philosophy was concerned with causality. From the religious point of view, the most important figure was Aristotle because his ideas were adopted by Christians and Muslims in the Middle Ages, and his categories are still a part of some schools of Christian philosophy. Aristotle identifies four types of cause:

1. Material (*causa materialis*)
2. Efficient (*causa efficiens*)
3. Formal (*causa formalis*)
4. Final (*causa finalis*)

To illustrate these, consider a house, according to Aristotelian notions of causality.

1. Material: the bricks, mortar, wood, glass, etc.
2. Efficient: the action of the workers who built the house.
3. Formal: the blueprint, the design by which the construction was guided.
4. Final: The owner wished to have a pleasant place to live.

Of these four, only the efficient cause survives in science today. The study of final causes was considered important in the Middle Ages, but it was attacked savagely during the Enlightenment, even though vestiges survive today, often well disguised.

Disagreement about predestination came to a focus in the dispute between Augustine (for predestination) and Pelagius (against it). The former was the clear winner, since he became Saint Augustine, while one speaks of the Pelagian heresy.

In the thirteenth century, Thomas Aquinas took full advantage of manuscripts previously unknown in the West to understand Aristotle and to incorporate his ideas – including those on causality – into his systematic theology. He used causality as one category of proof for the existence of God: For every effect, there is a cause; but a cause is also an effect; by induction there is a chain of causality; either it is an infinite regress (absurd), or there is an uncaused cause, a First Cause, called God.

In the Reformation period, Martin Luther, John Calvin, and Huldreich Zwingli were all strongly in favor of causality and predestination. Luther engaged with Erasmus of Rotterdam (opposed to predestination) in an exchange of treatises on predestination; neither one convinced the other. Confessional documents of the Reformation era appeared among the religious groups of Western Europe. In 1530, the Augsburg Confession (Lutheran) was written and presented publicly by Philip Melancthon. It was very diplomatic about predestination, too much so for Luther. In 1547, the Roman Catholic Church in the Council of Trent adopted similar statements. In 1562, the Church of England adopted the 39 Articles of Religion, of which several deal with predestination; there too an inclusive spirit prevailed, trying to contain a broad spectrum of opinions in the Church. The Lutherans continued to argue over predestination until 1575, when they adopted a Formula of Concord, which was conciliatory toward both sides of the issue. Calvinists met in 1620 at Dordrecht in the Netherlands (Synod of Dort) and adopted a strongly predestinarian statement.

By this time, the state churches of Western Europe had taken a stand, and it was in general forbidden that theologians should debate any more about predestination. Such strictures have been largely ignored in America.

Causality During the Enlightenment

The seventeenth and eighteenth centuries saw a great emphasis on rationality and a rejection of Aristotelian causal categories except the

efficient cause. God was seen as possibly the First Cause, but beyond that no divine action was considered as more than superstition. This is essentially Deism. The action of objects in the world was considered as if they were mechanisms driven by rather impersonal forces, much like cogs in a machine. Political and economic freedoms were mostly not valued, and determinism in nature was accepted, with mechanics as the foremost branch of science.

Descartes, Galileo, and Spinoza were intellectual leaders, pointing the way toward mechanism and determinism. Newton and Huygens formulated mathematical systems for this cause. Newton's laws became the model of enlightenment because they contained the essence of a causal and deterministic outlook.

Newton's second law, $F = ma$, force equals mass times acceleration, takes causal form because acceleration is the second derivative of the spatial position of an object. In other words, velocity is the rate of change of a coordinate, and acceleration is the rate of change of the velocity. If the position and velocity of an object are known at a particular time, and if the forces are known, it becomes possible to calculate the position and the velocity for all subsequent times, and also to calculate backward in time to learn the past history of the object. This condition of the knowledge is mathematical determinism. By the end of the eighteenth century, it was widely accepted as the way the world works.

David Hume wrote on causality and did not repudiate Newton. His writings had a great influence on Immanuel Kant, who examined every aspect of causality that was accessible at that time (Torretti, ch. 3). Hume added further causal conditions, most notably the requirements of sequence and contiguity. Both of these appear to be plain common sense: The cause must precede the effect, and effects such as telekinesis and levitation are excluded. Although it is attractive to insist on contiguity (objects must touch to cause anything), there is a problem when a force such as gravity acts across a distance. The sun's gravitational attraction keeps the earth in orbit, yet the earth and the sun are not contiguous. Newton was aware of this problem, and he did

not know how to explain it. Newton and Hume had little choice but to ignore it.

Alternative Formulation: Fields

The problem of action at a distance is also present for magnets and for electrical charges. The best description of the situation was developed by Michael Faraday, who described magnetic forces by using a force field. Magnet A sets up a magnetic field in its surrounding space. Magnet B interacts locally with A's field, and we say that B experiences a force from A. But Magnet B also sets up a field that locally causes a force on A. These two forces are equal in magnitude and opposite in direction, just as Newton's third law requires.

The field concept works just as well for electrostatic forces and gravitational forces. James Maxwell showed how the electric and magnetic fields fit into a set of four interlocking equations. Attempts to integrate gravity into the system have failed so far. However, the forces described by these fields continue to describe a causal and deterministic motion.

Alternative Formulation: Global Theories

The idea that it is important to maximize or minimize some value goes back to Newton and to Wilhelm Gottfried Leibniz, both of whom invented calculus to do this. One of Leibniz's disciples, Moreau de Maupertuis, tried to formulate a quantity that he called "action," calculated by adding contributions from all of the space; minimizing the action would then give you the answer to how the system behaves. For both personal and professional reasons, Maupertuis made enemies, one of whom was Voltaire, whose novel *Candide* was a biting satire of Leibniz, Maupertuis, and their ideas. Voltaire believed that their attempts to maximize or minimize asserted that we live in the best of all possible worlds, an idea he found easy to ridicule.

Although the formulation by Maupertuis was a bit confusing, his scientific endeavors had considerable merit, as was shown by Leonhard Euler and Joseph-Louis Lagrange. By more carefully defining the action, Lagrange was able to set up a well-posed problem of minimization, and by using Euler's calculus of variations, he was able to find the minimum. In doing so, he found, Newton's second law appears. Thus, a global principle of least action – which is not manifestly causal – leads to the same causal equations of motion that arise from the local theory of Newton, valid point by point.

Subsequent developments have shown that the global approach can be quite powerful provided that the action is properly defined. The global approach not only can reproduce the results of the local one, but it sometimes provides additional insight and information that theories based on a single point cannot produce.

Pierre Simon de Laplace

In the period of the French Revolution and the Napoleonic Wars, an important scholar of causality was Pierre Simon de Laplace (Gillespie 1997). His treatise on celestial mechanism carried Newton's mechanics to an impressive level of understanding of the motions in the solar system. In particular, he proved the stability of the solar system against small perturbations, and demonstrated that Newton's laws were more impressive than Newton himself had realized. He articulated the idea of Laplacian determinism, which states that given the initial conditions, you can use Newton's laws to predict the subsequent motion.

It is interesting that Laplace, famous in his own time for the causality of mechanics, should have achieved more lasting fame for his work on the theory of probability. He was not the first to attack the subject. The Bernoulli family placed probability on a good mathematical basis. The motivation for studying the systematics of multiple events, supposedly random and noncausal, was initially aimed at dice and card games. Laplacean probability does not really examine whether the randomness is ontological or simply

based on the impossibility of predicting outcome for a sufficiently complicated system. Dice are a Newtonian mechanical system, and therefore ought to be predictable, except that (1) the initial conditions are not properly known, and (2) the calculations are too difficult. So it is better to assume an aleatory system and analyze it as such.

With the rise of statistics as a mathematical tool to study aleatory systems, there arose a problem that needs to be noticed. Sometimes two types of events seem to be associated, and statistical tests show that they are correlated. But correlation does not prove causality. It could be that both events are caused by the same prior cause, and that neither one is the cause of the other. The Latin adage is actually false: *post hoc ergo propter hoc* (after this therefore because of this). It is a fallacy to be avoided.

Statistical Mechanisms

Physicists such as James Maxwell, Ludwig Boltzmann, and Josiah Willard Gibbs invented statistical mechanics to describe a system of many particles, each of which moves according to the laws of classical mechanics. The motion is causal at root, but by treating the motion as if it were random, one can use statistics to describe the entire system on the average. The results frequently agree well with observations, especially for many commonly encountered gases at room temperature and one atmosphere of pressure.

By the early twentieth century, the satisfaction with statistical mechanics was badly undermined by annoying discoveries of which we list three outstanding examples: (1) Classical statistics fails dismally to predict the shape of the electromagnetic spectrum. Max Planck in 1900 finally succeeded in getting agreement with experiment by introducing packets of energy, which he called *quanta*, to replace the classical idea that energy can come in whatever size you like. (2) The specific heat of a solid at very low temperature does not follow any rational classical form. Albert Einstein used Planck's distribution to improve the situation, but there was still measurable

discrepancy. Pieter Debye's theory went further in the direction of quantization to fix things up. (3) The behavior of electrons in a metal is quite far from the predictions of classical statistics. Enrico Fermi in the 1920s used quantum ideas to gain the needed understanding.

Quantum Mechanics

The need for a better theory than classical mechanics was evident by the 1920s, and for reasons beyond the examples listed above from statistics. The atomic theory of Niels Bohr, based on classical mechanics but with the ad hoc addition of quantized angular momentum, was not a satisfactory answer. There was need for something new.

In 1925, Werner Heisenberg pointed toward a new theory (quantum mechanics, or QM) by positing that one should use only quantities that are observable. This start (somewhat misguided) was good in that it removed the classical Bohr orbits from the center of attention. It motivated Paul Dirac to invent a particular type of noncommuting algebra that led to better insights. In 1926, Erwin Schrödinger constructed his wave equation to accomplish the same things that Dirac and Heisenberg were doing. Multiple papers appeared that year showing that the three approaches were equivalent.

In the summer of 1927, Heisenberg showed that the formalism of quantum mechanics implies the famous principle of uncertainty: The position and the momentum of an object cannot be known simultaneously to arbitrary accuracy. Hence, the requirement for classical determinism cannot be satisfied, and the motion can never be fully determined. At the Solvay Conference in Brussels in October of 1927, there was a titanic struggle between Einstein (determinist) and Bohr (indeterminist). Neither was able to shake the other's firm beliefs (Moore 1966, 163 *et seq.*). The debate went on for another 8 years before it finally subsided, mainly because Bohr's interests had changed toward the phenomenology of nuclear physics. With a few exceptions, physicists active today agree that Bohr was right and Einstein was wrong.

People still argue about the detailed interpretation of quantum mechanics, but there is broad agreement about the outlines, including indeterminacy.

How firm is the uncertainty principle? It is very robust. It follows by airtight logic from the basic assumptions of quantum mechanics. If we wish to deny the uncertainty principle, we have to abandon quantum mechanics, and we will be left with no working theory of molecules, atoms, nuclei, and subatomic particles. That price would be too high.

As a way to save both quantum mechanics and determinism, it has been suggested that there are *hidden variables* that are deterministic in their nature, but which can mimic the result predicted by the Schrödinger equation. A definitive test was performed experimentally by Alain Aspect and his coworkers; they found strong evidence against hidden variables in favor of conventional quantum mechanics.

Quantum Mechanics: Evidence Against Causality

The argument against causality begins with the uncertainty principle. For a single particle constrained to move in one dimension, the uncertainty principle states that $\Delta x \Delta p \geq h/4\pi$ where x is the position, p is the momentum, and h is Planck's constant; the symbol Δ means "standard deviation" or uncertainty.

It is permissible in quantum mechanics to narrow down and refine your knowledge of the position coordinate. In doing so, you will thereby lose information about the momentum. Similarly, you can know the momentum to great precision, but you will not know much about where the particle is.

In classical mechanics, one can construct a two-dimensional space with coordinates x and p . The particle's initial state is represented by a point in this space (phase space); its motion, governed by Newton's laws, is a curve in phase space. (Phase space: for a system of N particles, the $3N$ -dimensional space of the coordinates is called configuration space. If the $3N$ components of the momenta of these particles are added, the

resulting 6N-dimensional space is called phase space.) In quantum mechanics, the idea of a single point in phase space is without meaning. The initial state of the particle appears as a cloud of points in phase space in an area at least as big as $h/4\pi$. The density of the cloud is nonuniform; its local density is given by the square of the wave function at that point.

If the problem is generalized to allow motion in three dimensions, then the three components x , y , z of the particle's position will have uncertainty relations with their respective components of momentum p_x , p_y , p_z . There is no uncertainty relation between, say, x and p_y .

The energy E of the particle has a conjugate relation with the time t , and so there is the relation $\Delta E \Delta t \geq h/4\pi$. This relation comes into play when physicists try to study very short-lived particles. If a particle's lifetime is so short that the time of its decay is known rather accurately, then the measurement of the energy will be correspondingly inaccurate.

One extreme case is given by resonances in the scattering of pi mesons from protons. The cross section (a measure of the probability) of the scattering increases rapidly from low energy and peaks when the energy (in the center-of-momentum system) is about 1,240 MeV (million electron volts). The peak is quite broad, $\Delta E = 120$ MeV, corresponding to a time interval of 10^{-23} s (seconds). The usual interpretation of such resonances is that they are really particles with very short lifetimes, and therefore, there is considerable uncertainty in their mass (energy).

An example of the opposite sort is provided by a continuous-wave laser, where the photons have a long time interval for their production and extremely well-defined frequency.

Another important example of noncausal phenomena in QM is the case of an electron in an excited state of an atom. If the excitation energy is high enough, there may be several states, including the ground state, of lower energy. For one such electron, QM cannot tell you into which state it will make its downward transition, nor can it tell exactly when the transition will occur. What it can do is to calculate the respective probabilities of the various transitions and also

the mean life of the excited state. When such calculations are performed for atoms, the results agree with experiment. For example, of two transitions, if one is twice as probable as the other, the more probable one will appear as a spectral line twice as bright as the other.

Quantum Mechanics: Evidence for Causality

Although the spirit of quantum mechanics is probabilistic or aleatory, there are some ways in which it describes behavior with certainty.

A particle whose wave function is known at a specific time for all points in space will propagate in space in a very predictable way, as long as external forces are absent. This statement is a direct result of the time-dependent Schrödinger equation; it is in a sense the quantum version of Newton's first law of motion.

Occasionally, one encounters a quantum system that is unstable and that has only one decay option. In that case, it is perfectly predictable which option will occur, but it is still not possible to predict the precise time when the decay will occur.

For many systems that obey quantum statistical mechanics, the average behavior will be based on enough particles so that the uncertainty in the motion will be quite small, and the system will be deterministic. It is effectively at the classical limit, and the predictive power of Newton's laws will appear.

Monte Carlo Calculations

An interesting and useful technique for computation is called Monte Carlo (for the famous gambling center) because it is based on randomness. One uses random numbers in quantity to simulate something which could perhaps be modeled by an analytic calculation, but where the accuracy achieved in a given amount of computer operation is greater for the Monte Carlo method.

A simple example would be to calculate the value of π by using random numbers. Consider a circle of radius equal to unity, centered at

the origin of coordinates. A square is circumscribed about the circle with $-1 < x < +1$ as the mathematical definition. Generate random numbers in pairs, uniformly distributed between -1 and $+1$; call them x and y . Then calculate $x^2 + y^2$; if the result is greater than 1, discard it; if less than 1, keep it, and keep track of the total number of pairs generated. The fraction of keepers will be $\pi/4$. The more trials you make, the more accurately will your answer resemble the correct one.

The simple example of a circle converges to the correct answer slowly enough that one should really do the calculation some other way. That is because the example is in essence two dimensional; Monte Carlo converges more slowly than other methods until you encounter a problem with five or more dimensions, and after that, it is faster than most other methods.

Monte Carlo is in essence a method of integration, i.e., finding areas, volumes, or hypervolumes.

A serious question arises in computer calculations using Monte Carlo. Where does the computer get a large supply of random numbers in a short time? The customary answer is to use a multiplicative congruential method. A suitable chosen number is caused to multiply another suitably chosen number many times, and each successive result is the next random number. These numbers are of course not truly random: They are perfectly causal, but the casual observer cannot see the connection. The numbers are called “pseudo-random.”

It happens that there are potentially harmful correlations in pseudo-random numbers from multiplicative congruential generators. This fact was discovered by George Marsaglia, who also discovered the cure: Use a different multiplicative congruential generator to do a pseudo-random shuffle of the numbers from the original one.

Causality and Chaos

It seems illogical that a causal, deterministic device such as a properly operating digital

computer could ever produce random numbers. The pseudo-random sequence that comes from a computer is in fact totally deterministic, but it passes certain statistical tests for randomness.

Chaotic systems are quite analogous. They are governed by the laws of classical mechanics and should thereby be deterministic. Yet they exhibit behavior that appears wildly unpredictable.

A simple example is a pendulum with a magnet at its end, allowed to swing freely in what is basically two dimensions, the two angles that it takes to specify the instantaneous location of the pendulum. Two (or more) additional magnets, placed just below spots where the pendulum can go, complete the arrangement. If the pendulum is released and allowed to swing freely, the motion is surprisingly unpredictable.

Many other examples of chaotic behavior could be listed: (a) Population dynamics in biological systems provides many specific types. (b) The earth's atmosphere is a chaotic system that renders impossible accurate predictions of weather more than a few days in advance. (c) If 15 billiard balls are placed in an equilateral triangular array and then struck with a sixteenth ball (the cue ball), the resulting motion is quite unpredictable. The list could be continued.

All these chaotic systems share a few important properties: (a) Their motion is inordinately sensitive to initial conditions. (b) Their equations of motion contain nonlinearity. (c) They mostly move in a phase space of three or more dimensions. (Population dynamics is an exception, since it is governed by a nonlinear difference equation rather than a differential equation). (d) Their time evolution ought to be causal and deterministic, but in practice, it is not.

In these nonlinear systems, there is typically some parameter (or set of parameters) that can be adjusted, along with the initial conditions. It very often happens that there are regions in phase space that correspond to stable and predictable motion, and likewise, there are regions of phase space that are characterized by unstable, chaotic behavior. There is a boundary between these two regions, and it is here that some of the most interesting phenomena occur (Kauffman 1995, Ch. 6). It appears that life itself is

a phenomenon associated with the boundary between order and disorder.

Cerebrovascular Diseases

M. G. Hennerici

Department of Neurology, University of Heidelberg, Universitätsmedizin Mannheim, Mannheim, Germany

Diseases of the nervous system covered by neurology mainly affect the brain, spinal cord, peripheral nerves, and muscles. Different mechanisms contribute to focal or global brain lesions which today can be diagnosed based on clinical signs and symptoms, the history of onset, follow-up with progression or recovery and rehabilitation, modern brain imaging, and neurophysiological as well as laboratory investigations. Management and emergency or intensive care treatment are based on neurobiology, neurophysiology, pathophysiology, and clinical study evidence.

Stroke is one of the most frequent diseases treated by neurologists in industrialized countries of North America, Europe, Asia, and Australasia. This disease has been known since the times of Hippocrates (about 400 B.C.) who already observed that many blood vessels connected the brain – he believed they were filled with air providing the spirit of mankind: He considered interruptions of this air flow to be responsible for hemiplegia and convulsions with paralysis of the right arm and the loss of speech (probably the first written account of aphasia) as already described in his *Epidemics*. This was confirmed later by Galen who attributed *apoplexia* to an accumulation of phlegm in the arteries once this obstructed the passage of animal spirits within the ventricles. However, it took more than 1,500 years until the discovery of the anatomy of the brain from dissections by Andreas Vesalius (1514–1564) and his outstanding artist Jan Stephan Kalkar

Cerebrovascular Diseases, Fig. 1 Thomas Willis (Wikimedia Italia)

who in their book *Fabrica* presented outstanding neuroanatomical diagrams in copper plates and woodcuts. Thomas Willis (1621–1675) (Fig. 1) indeed coined the term *neurology* taking its root *neuro* from the Greek in his *Cerebri Anatome*, although the structure for which he is still remembered was actually described earlier by several others, such as Gabriel Fallopius (1523–1562), Johann Vesling (1595–1649), professor of anatomy and surgery at Padua, and Johann Jacob Wepfer (1620–1695), a Swiss physician from Schaffhausen, who was affiliated to a convent where he was able to follow his patients from disease to autopsy. Actually Wepfer's vascular anatomy of the brain in his *Historiae apoplecticum* described the polygon of arteries at the bottom of the brain already years before Willis. In addition, he identified the carotids penetrating from the extra- to the intracranial space forming a segment now known as carotid siphon. His insight into clinical correlations was also advanced over his time since he reported on the sudden clinical manifestations secondary to carotid artery blocking as well as bleeding into the brain as causes for apoplexy and was the first to emphasize the association of speech disorders with right hemiplegia

based on his anatomical observations. His name continues to be associated with stroke in our days: Since 2005, the European Stroke Conference annually honors outstanding contributors to clinical and/or experimental stroke research with the most prestigious stroke award available, named Johann Jacob Wepfer Award (www.eurostroke.eu) (Fig. 2).

Despite increasing efforts during subsequent centuries, it took another 500 years to understand and acknowledge the importance of cerebrovascular diseases in neurology and medicine: Stroke is the third leading cause of mortality and the second one of economic burden worldwide due to its frequent lack of full recovery and impact on dependency of its victims.

Only since more than a few decades ago, the management and prevention of cerebrovascular diseases became the most challenging task for neurologists because of an estimated prevalence in Europe of nearly 10 million people. Worldwide stroke kills an estimated 5.7 million people annually, it is a major public health issue and among the leading causes of immobility and long-term disability. There are two main types of stroke, the most common is ischemic stroke caused by thromboembolic clots narrowing or blocking blood vessels (about 80%), followed by hemorrhagic stroke caused by bleeds from blood vessels in the brain or in the subarachnoid space (about 20%). With increasing age, hemorrhagic stroke becomes more frequent and is estimated to grow within the next decade up to 30%. The onset of stroke is often sudden; however, about one third of the patients present with warning signs followed by immediate full recovery within minutes or a few hours (so-called TIAs – transient ischemic attacks). Although TIAs have gained increasing public awareness, they are often misinterpreted as benign events although the immediate risk of permanent stroke after a TIA can be as high as eight- to tenfold within a few weeks after the qualifying event in the presence of active carotid or cardiogenic sources of embolism. It is, therefore, important to seek emergency advice in a specialized stroke center, whether or not full recovery of symptoms occurs. This new management of stroke has decreased

mortality significantly. Furthermore, acute treatment of patients early after onset in stroke units and comprehensive stroke centers has improved the chances for full recovery and independence strikingly, mainly because of early thrombolysis of acute ischemic stroke. Increase in public awareness has advanced general knowledge about risk factors, early signs of symptoms, and potential treatment facilities: *Time is brain and stroke is an emergency* has been coined for health care strategies and information in the newspapers, television, and advertisements. Consequently appropriate diagnosis and treatment has been disseminated around the world by multiple professional medical specialties including paramedics, emergency and general physicians,

neurologists, internists, clinicians, physiotherapists, speech therapists, etc.

However, with increasing age, cardiogenic causes of ischemic stroke have also increased and along with small vessel diseases today contribute to more than 50% of stroke etiologies potentially leading to vascular dementia. Risk factors of atherosclerosis such as hypertension, hyperlipidemia, smoking, diabetes mellitus, and anticoagulation disorders increase with aging but are already present in younger stroke victims. People with risk factors for stroke need careful control and regular advice with regard to medication and recommended lifestyle changes. The value of physical activity as well as continuous mental and cognitive activity has only recently

been addressed scientifically both in experimental and clinical studies. There is no doubt about their effectiveness in stroke prevention and strategic capacity of best aging. Lifestyle changes should be added to modification of risk factors and urgent action should be taken both for primary and secondary prevention (of recurrent stroke after a qualifying event). High blood pressure should be lowered ($<130/80$ – 85 mmHg), and diabetes mellitus be controlled to maintain HbA1c values below 6.5% levels. People with cholesterol levels >190 mg/dl and cardiovascular disease, including TIAs/stroke, are likely to benefit from cholesterol-lowering regimens as do patients with multiple risk factors, requesting statins in many conditions. Smokers can reduce their overall risk of cardiovascular mortality and morbidity considerably by cessation of smoking, and alcohol intake should be limited to reasonable doses. By the age of 55, healthy people should regularly be controlled for silent cardiovascular disease; in particular, they should undergo regular noninvasive diagnostic testing in order not to oversee developing diseases such as atrial fibrillation and atherosclerosis.

Mechanisms of recovery and rehabilitation are by far better understood than 10 or 20 years ago and offer a spectacular potential for patients with focal disturbances of sensori-motor and neuropsychological deficits. This is of utmost importance because neurodegeneration and vascular diseases of the brain coincide in the elderly and cause multiple cognitive problems and changes in personality: Emotional disturbances, depression, psychomotor retardation slowing of executive cognitive function as well as decline of intellectual power may all limit people's independency and are among the most feared and disastrous complications in otherwise healthy aging populations.

Diagnostic instruments have improved and contributed to much better strategies in stroke prevention and treatment. Based on clinical signs and symptoms, they are prepared to identify sources and degree of brain lesions quickly and noninvasively without producing harm to the patient in the acute condition. In addition, identification of subjects at risk for recurrences is of the

utmost importance as is the correct interpretation of signs of stroke: Complete infarction in the largest territory of the middle cerebral artery (MCA) is a life-threatening event and can cause deviation of the head and eyes from the hemiplegic side involving face, arm, and leg, sometimes along with hemisensory loss and homonymous hemianopia. Dominant hemisphere lesions produce various sorts of speech disturbances (aphasia) while nondominant hemisphere lesions produce contralateral neglect with dysarthria, sometimes dysphagia and impairment in spatial orientation. It has to be mentioned, however, that occlusions of branches of the MCA can cause quite strange, sometimes misdiagnosed or even silent deficits, i.e., non-fluent speech, impaired repetition ability, calculation failures, body texture abnormalities, position sense disturbances, etc. Emotional apathy and constructional impairment, mutism, abulia, muteness, and reduced spontaneity may result from branch occlusions of the anterior cerebral arteries, and memory disturbances, illusions, cortical blindness, and agitation are characteristic signs resulting from occluded branches of the posterior cerebral artery, all sometimes difficult to identify.

Spontaneous intracerebral hemorrhage (ICH) accounts for 10–15% of all strokes and has a higher mortality rate than ischemic stroke or subarachnoid hemorrhage (SAH). Most frequent causes are hypertension, cerebral amyloid angiopathy, coagulopathy, vascular anomalies, tumors, and drugs; however, hypertension is the greatest modifiable risk factor for ICH.

Bleedings into the vessel walls (so-called dissections) and blockage of draining veins and sinuses are common causes of hemorrhagic stroke in younger men and women and may be overlooked both by patients and nonexpert healthcare people. Once severe ICH has occurred, treatment is still limited, unfortunately. This is to some extent also true for SAH, mainly caused by aneurysmal bleedings (80%) from ruptured formations. In the older literature, saccular aneurysms are sometimes called “congenital” which is misleading; although a hereditary defect of the vessel wall is likely to contribute foremost, aneurysms develop during the course of life, enlarge over

years to decades until they become symptomatic in young and middle aged patients. Today they can be identified in advance by noninvasive vascular/brain imaging (CTA/MRA). However, it is largely unknown why some patients develop aneurysms and others do not. Surgery may be indicated in patients with a high risk for bleeding complication and after SAH in the presence of multiple aneurysms.

In summary, the history of stroke and cerebrovascular diseases covers more than 2000 years of well-known but misunderstood clinical signs and symptoms. Emergency management, prevention of first ever and recurrent events has only very recently been achieved. Today we are faced with challenging questions about recovery and rehabilitation as important mechanisms of brain reorganization and plasticity anticipating healthy aging as well as repair mechanisms after detrimental lesions. With increasing age of modern populations, neuro- and vascular degeneration of the brain will become a major issue for translational research (= basic experimental and clinical research) to prevent people from dementing illnesses causing disastrous cognitive decline and loss of intact personality.

Chan

Steffen Döll

Japan Center, Ludwig-Maximilians-Universität München, Munich, Germany

Description

The term “Chan” contracts *channa*, the Chinese transliteration of Sanskrit *dhyāna* or meditation/contemplation. Chan denotes a school of Chinese Buddhism that, generally speaking, values meditative insight over scholastic knowledge. Chan denies to be based on scriptural exegesis (as is the case with all the other schools of Buddhism) and therefore sees itself as a unique – and superior – tradition within Buddhism in general. Its key concepts are those of transmission and immediacy.

This entry will present Chan in terms of its intradenominational characterization, its hagiography, its religious practice, and its relevance as an object of scholarly analysis.

Characteristics

Central to Chan’s self-representation is the claim that the Buddha transmitted not only teachings as pointers toward and mediations of truth but also awakening itself as immediate realization of truth. The transmission of awakening is based on direct communication between the heart of the Buddha (and/or his successors, the so-called Chan patriarchs, *chanzu*) and the heart of the disciple. This process is commonly called “using the heart to transmit the heart” (*yixin zhuanxin*) and crystallized in a lineage of Chan teachers who took custody of awakening, passing it on unaltered through the ages. Thus, every Chan practitioner, if a part of this enlightened tradition, has access to the same awakening that the Buddha himself had experienced.

Chan is, in general, critical of what is taken to be the scholastic profanization of language and hesitant to employ discursive and argumentative

prose. This is because in light of the importance of heart-to-heart transmission, the communication between master and disciple holds soteriological significance that supersedes linguistic interpretation or textual analysis. The disciple is urged, not to intellectually understand a certain dogma but to transform her existence precisely by abandoning the intellect's restrictions. Specific communicative models include nonverbal elements (blows, gestures, silence, shouts, etc.) as well as sophisticated verbal strategies (anecdotal and poetic quotations, seemingly random interjections, pithy remarks, spite, etc.). These are used to weaken the student's rational attachment to self and world. Having deconstructed rationality as the main impediment to immediacy, the student is referred to the ancient patriarchs and her present master as objects of mimesis. Awakening is, in a manner of speaking, rehearsed mimetically, and at some point, the student achieves the same immediate realization of truth as the Buddha. She is then acknowledged by her master as a follower of the Chan tradition and thus a direct successor of the Buddha himself.

In summary, by traditional account, Chan:

- Establishes neither words nor letters
- Is a separate tradition beyond the teachings
- Points directly to the human heart
- Reveals awakening in every practitioner's nature and perfects the Buddha

Hagiography

In keeping with the pivotal role accorded to authentic transmission, Chan relies heavily on anecdotes that present the ancient masters as blueprints of impersonated enlightenment. This tendency resulted in a vast corpus of anecdotal literature that typically belongs to the "recorded sayings" (*yulu*) genre. These texts form an integral part of Chan's self-understanding and concisely outline its hagiography. Some examples shall be given below.

In the traditional account, the Buddha, having awakened to the ultimate truth by way of silent meditation, began his teaching career. But as his awakening surpassed the limitations of

verbalization, his teachings could not but remain at the level of mere approximation, relative in nature, and as such incongruent with the absoluteness of reality. Out of this incongruity, Chan derives its founding myth: On one occasion, instead of delivering the expected sermon, the Buddha simply presented a flower to his congregation. This met with incomprehension in every but one case: Kāśyapa, a long-standing disciple of the Buddha, smiled in understanding. Thereupon, the Buddha declared that a transverbal transmission had taken place and that Kāśyapa was to be revered as his successor and the future custodian of awakening (Wumenguan 2005, case 6).

Through Kāśyapa, a lineage of transmission had formed that in its 28th (sometimes also 29th) generation reached China in the person of the Indian monk Bodhidharma around the turn of the sixth century. When Bodhidharma had spent 9 years in unbroken and motionless meditation inside a cave, he accepted his first disciple (though only after the latter had cut off his own arm below the elbow to prove his determination; Wumenguan 2005, case 41). Thus, Bodhidharma came to be regarded as the founding father and first Chinese patriarch of Chan. His exchange with emperor Wu of Liang (r. 502–549) is among the most famous of Chan anecdotes. Upon their first meeting, the emperor, being an ardent supporter of Buddhism, inquired as to how many merits his considerable endowments had earned him. Bodhidharma cut him short: "No merits at all." When the emperor then asked about the nature of truth, Bodhidharma again gave a short-spoken answer: "Everything lies in plain view, and nothing sacred is in sight" (Biyanlu 2003, case 1), thereby thoroughly negating the possibility to earn merits, rationally explain truth, or speculate on the underlying nature of reality.

By the Tang dynasty (618–907), a Chan community had begun to grow on Chinese soil that over the years drew more and more followers. The fifth Chinese patriarch, Hongren, supervised a congregation of considerable size but was unable to decide on a suitable successor. Having called on his advanced students to give expression to the profundity of their insight in rhyme, he praised his disciple Shenxiu's work above all

others: “The body is the *bodhi* tree under which the Buddha had his awakening, and the heart is like a bright mirror’s pedestal. Take pains to always wipe it clean! Let no speck of dust settle upon it!” However, Huineng, an illiterate kitchen helper, heard about these verses and in reply had his own version inscribed on the monastery’s walls: “Actually, there is no tree in awakening, and a pedestal has nothing to do with the bright mirror. Originally, there is not a single thing. So how could there be any place for dust to settle upon?” (Liuzu tanjing 2008) Officially, master Hongren scolded Huineng for his temerity but in secret revealed him to be the actual inheritor of the Buddha’s awakening.

Subsequently, a dispute over the patriarchal succession arose, and Chan was divided into the Northern school of Shenxiu and the Southern school of Huineng. As the quotation above indicates, matters came to a head over the ideological issue of whether enlightenment was a gradual process (the Northern position) or a sudden breakthrough (the Southern position). Within only a few decades, the gradualist position had relegated into other, more speculative and scholastic traditions. Subitism became the only ideological and rhetorical standard for Chan. Even today, every existing lineage traces itself back to Huineng as sixth patriarch and adheres to the sudden enlightenment approach he advocated.

A series of great masters furthered Chan’s development in the eighth and ninth centuries and produced parallel lineages: the so-called Five Houses (*wujia*) with distinct “family styles” (*jiafeng*). These ranged from metaphysical speculation (Caodong faction) to eclectic considerations about the fundamental unity of Buddhist diversity (Fayan/Yunmen factions) and to radical antinomianism (Linji/Guiyang factions). These diverse readings of what constitutes the Chan tradition dominated the general Buddhist discourse in China well into the Song dynasty period (960–1279). Under the guidance of the Five Houses, Chan reached its apex. Later Chinese developments are traditionally regarded as mere repetitions at best, deteriorations at worst. In this mature form Chan was transmitted to Japan (where it is called Zen) in the late twelfth and

early thirteenth century and was made known internationally in modern times.

Nowadays, Chan remains a dynamic, even vibrant tradition in Taiwan and continues to draw followers also on the Chinese mainland. It has had major influence on the development of Korean Son, Japanese Zen, and meditative forms of East Asian Buddhism as received in the Americas and Europe.

Practice

In terms of practice, Chan relies heavily on seated meditation (*zuochan*; hence its name). Roughly speaking, two different meditative techniques may be distinguished:

- Insight into an Anecdote (*kanhua*): The master presents her disciple with an anecdote or a rationally irresolvable dilemmatic question (a so-called *gong’an*, literally “public notice”) which forms the basis of meditative practice.
- Silent Illumination (*mozhao*): Practice is reduced to silent, objectless sitting meditation; prolonged practice produces spontaneous enlightenment.

Beyond these, however, in Chan monasteries – while entertaining close ties to a considerable community of lay followers, Chan has developed forms of monasticism that have had major impetus on the general development of Buddhist institutions in East Asia – there is also an array of rituals that may be employed in varying degrees. These include work around the buildings and gardens (*zuomu*), one-on-one encounters with the master (*canchan*), question-and-answer sessions (*wendang*) during which a student’s doubts are addressed or her enlightenment put to the test, recitation of scriptures (*kanjing*), teachings and interpretative readings by advanced monks (*fayu*), and observations on memorial days, prayer, social work, etc. If based on the proper Chan-like attitude, all these are seen as spiritual practices of equal value.

Criticism

While the traditional narrative outlined above remains unbroken in denominational circles,

Chan's self-characterization in terms of authenticity and immediacy has increasingly been challenged from philological and historical perspectives and in academic circles is counted as a hagiographical and ideological construct. This antitraditional reading of Chan became possible, above all else, by the discovery of a large corpus of Chinese manuscripts dating from the fifth to the eleventh centuries in a sealed cave near the Silk Road oasis of Dunhuang (Gansu prefecture, western China) in the year 1900. This corpus included several hitherto unknown Buddhist texts that shed new light on the historical development of Chan and resulted in the acknowledgement that Chan had to be seen not as a transhistorical absolute but as a phenomenon in historical context (cf. especially the groundbreaking studies by Yanagida Seizan (1922–2006)). In scientific terms, Chan is, far from being a manifestation of unchanging reality beyond the contingencies of time, a relatively late development in the history of Buddhism that draws on a plurality of sources for inspiration and legitimation.

While this viewpoint has met with considerable resistance from the believers' side (cf. the dispute between Hu Shi (1891–1962) and Suzuki Daisetsu (1870–1966) in *Philosophy East and West* 3/1 (1953)), the “Golden Age” of Chan iconoclasts during the Tang era has been proved to be a mythological construct. For the sake of securing religious prestige – and actual political power as well – Song dynasty adherents of Chan developed a narrative that allowed them to present their own tradition as the superior form of Buddhism. In consequence, Song Chan has come to command scholarly attention (cf. Gregory and Getz 2002; Schlütter 2008). At the same time, efforts continue to contextualize Tang Chan, resulting in the deconstruction of traditional hagiography (cf. McRae 1986; Faure 1991; Welter 2008). To give a few examples:

- Bodhidharma has been disclosed as a pan-denominational figure that is not only an anti-nomian Chan master but also incorporates ritual aspects as well as scholastic modes of argumentation.
- The schism between the Northern and the Southern school has turned out to be rather

a product of subitist rhetoric that attempted to marginalize gradualism and deny its influence.

- An analysis of the tenth-century texts has yielded data that the traditional focus on meditative experience and authoritative lineage had been challenged by scripture-focused approaches within Chan itself.
- Ritual has been emphasized as a main, if not the major concept in an analysis of Chan practice, casting doubts over the claim to radical iconoclasm and meditational authenticity (cf. Heine & Wright, 2008).
- Chan's self-representation has convincingly been shown to be a Song era and even later product that owes much of its present-day popularity to the missionary efforts of Suzuki and his epigones.

Thus, in recent years Chan has come to be understood less as a monolith of religious truth but as a historically conditioned, highly complex sociopolitical phenomenon. Its critical analysis continues to produce relevant insights into, among others, the historical relation between state and religion or society and tradition, respectively; the role of meditation vis-à-vis ritual in religious practice; strategic issues centering on the authoritative nature of scripture versus tradition; and problems in the transcultural reception of religions and ideas.

Energy; Entropy; Gibbs energy; Helmholtz energy; Rate of entropy production; Self-organization; Thermodynamics

Description

Thermodynamics originated from study of heat engines, engines that convert heat to mechanical motion. Prior to the invention and the use of steam engines (James Watt obtained a patent for his version of the steam engine in 1769), the machines of the eighteenth century were driven by wind, water, and animals: They transformed one type of motion to another. In contrast, the steam engine converted heat to motion: an entirely new way of generating motion, which heralded the industrial revolution. Only in the following century, when the steam engine's role in transforming society was plainly visible, was a systematic study of its fundamentals undertaken. The most significant contribution to this field came from Nicolas Léonard Sadi Carnot, who discovered the fundamental limits to the efficiency of heat engines that convert heat to mechanical energy. This line of work eventually led, in the hands of Rudolph Clausius, Lord Kelvin, and others, to the formulation of the Second Law of Thermodynamics. This law established the fundamental irreversibility of natural processes, or the arrow of time as an objective reality (http://en.wikipedia.org/wiki/Entropy_2999).

During the nineteenth century, with the new instruments that were constructed, heat, electricity, and chemical reactions were investigated and many new laws governing these phenomena were formulated. It also became evident, that all these phenomena were interrelated: Chemical reactions could produce heat (exothermic reactions), and heat could drive chemical reactions (endothermic reactions); so it was with electricity which could drive “electrochemical” reactions and vice versa; heat could generate motion and motion could generate electricity. While these interconnected processes were being investigated, the idea that there was one quantity, the energy, that was conserved in all these transformations was born. Many contributed to this concept, most notably, James Prescott Joule, Germain Henry Hess, Julius Robert von Mayer, and Herman von Helmholtz. This development and understanding of the concept of energy and

its conservation led to the formulation of the First Law of Thermodynamics, which states that in every transformation, total energy of all systems involved must be conserved; transformations in which the energy is not conserved do not take place in nature – though we can easily conceive of them.

The two laws of thermodynamics are the foundation of the subject. In the nineteenth century, Clausius, Kelvin, Gibbs brought all the contributions to the subject into coherent whole and formulated what is currently called *classical thermodynamics*. As will be shown below, this formalism made thermodynamics a theory of states and has no direct connections to the processes that transformed the states. Later, two other laws were added to the formalism, called the Zeroth Law and the Third Law. The Zeroth Law states that if system A is in thermal equilibrium with system B, and B is in thermal equilibrium with C, then A must be in thermal equilibrium with C. The Third Law gives us the means to assign an absolute value to entropy; it states that as the temperature approaches zero, the entropy of a system also approaches zero. Though these two laws are essential for the completeness of the formalism of thermodynamics, their physical consequences are not as far reaching as those of the First and Second Laws.

During the twentieth century, contributions to thermodynamics made by Lars Onsager and Ilya Prigogine made thermodynamics a theory of irreversible processes (Ji 2012; Kondepudi 2008). It related the production of entropy directly to natural processes and essentially restated the Second Law in terms of processes and gave us a way to relate the rates of production of entropy to the rates of processes such as heat flow. The contributions of Ilya Prigogine and his colleagues also gave us insight into the dual role of irreversible processes: as both *creators* and *destroyers* of order (<http://en.wikipedia.org/wiki/Entropy> 2009; Prigogine 1947). Thermodynamics has given us two fundamental quantities, *energy* and *entropy*, and two universal laws that govern them. The universality and practicality of these laws make thermodynamics one of the most important branches of human knowledge. And it

has raised profound questions about our universe, the arrow of time and the theory of evolution. In the twenty-first century, thermodynamics will find new areas, such as sustainable energy use and economies, to which it will contribute.

Heat and Energy. The concept of *kinetic* and *potential energy* and the conditions under which their sum, the total *mechanical energy*, is conserved was well known in the nineteenth century. This formalism also included the concept of mechanical work, which is defined as the product of force and the displacement of the body upon which the force acted. The unit for measuring mechanical energy was the erg. But the nature of heat was still under debate in the nineteenth century. The *caloric theory* of heat, which posited that heat was some sort of fluid, and the amount of heat was measured by its effect in raising the temperature of a substance; the unit for the measuring the amount of heat was called the calorie, a term still in use along with the term “calorimetry,” the science of measuring heat. On the other hand, the *mechanical theory* argued that heat was a measure of mechanical motion of molecules. The experiments of James Prescott Joule established the equivalence between mechanical energy and heat energy. With his carefully designed experiments, and state of the art calorimetry, Joule proved that when mechanical energy is converted to heat, there was an equivalence: The amount of heat generated was proportional to the mechanical energy or work in the conversion process, regardless of the means or method through which the conversion took place. This implied that the two quantities, mechanical energy and calories, are two measures of the same quantity, and that the calorie and the erg were measuring the same quantity – just as Celsius and Fahrenheit measure the same quantity, viz. temperature. Similarly, the measurement of energy in other processes, such as electromagnetic and chemical energies, can be proven to be equivalent. This has led us to the current SI (Système International) energy unit, which is the Joule. In the currently used of units (Système international units), Joule’s experiments established that $1 \text{ cal} = 4.18 \text{ J}$.

The First Law of Thermodynamics. The formulation of the First Law of Thermodynamics is based on the contributions of many scientists. One of the early contributions came from Germain Hess, who established the fact that heat released or absorbed during a chemical reaction, called the heat of reaction, depended only on the initial and final states of the system, and not on the manner in which the transformation was accomplished. This led Hess to the formulation of the law of additivity of heats of reaction: The total heat released or absorbed in an overall chemical reaction is equal to the sum of the heat released or absorbed in the chemical steps that constitute the overall reaction. This law enabled the chemists to assign energy to each chemical compounds and measure the changes in their energy in a chemical transformation. The law of Hess implies that the total amount of energy, chemical plus heat released or absorbed plus mechanical work (due to changes in the system's volume), remains the same during the chemical reaction. This is the law of conservation of energy in the field of chemistry.

Following the work of Joule, Hess, and others, Julius Robert von Mayer and Herman von Helmholtz suggested a universal conservation of energy, a quantity conserved in all natural processes. This is the First Law of Thermodynamics. Thus, every system could be said to have certain amount of energy, U . This energy is a state function, i.e., it depends only on the current state of the system, not on the manner in which that state was reached.

While it is true that our current understanding of the atomic structure of matter reveals that all energy is, in its essence, kinetic and potential, in practice, the measurement of energy is not based on this understanding. Indeed, the First Law of Thermodynamics can be formulated and could be stated entirely in macroscopic terms, regardless of the structure of matter. It is important to note that the laws of thermodynamics can be stated and verified entirely in macroscopic terms. The First Law of Thermodynamics or the law of conservation of energy is the cornerstone of science. It has withstood countless experimental tests. Even the existence of an elementary particle,

now called the neutrino, was predicted on the basis of this law and experiments confirmed the prediction. Any theory of natural processes that violates the law of conservation of energy is rejected as impossible.

The Second Law of Thermodynamics. The origin of this law can be traced back to 1824, when Nicolas Léonard Sadi Carnot, a brilliant military engineer, published a remarkable book, "Réflexions sur la Puissance Motrice du Feu, et sur les Machines Propres a Développer cette Puissance" ("Reflections on the Motive Force of Fire and on the Machines Fitted to Develop that Power"). In it he came to a far-reaching conclusion that eventually led to the formulation of the Second Law of Thermodynamics. Carnot analysis showed that while the energy of mechanical motion can all (100 %) be converted to heat, the inverse process, the conversion of heat energy to mechanical energy, has limitations. Carnot's work showed that maximum efficiency of conversion of heat energy to mechanical energy by a heat engine depends not on the mechanism of conversion but only on the temperatures between which it is operating. In contemporary formulation of thermodynamics, this upper limit of efficiency is expressed as $(1 - T_{\text{cold}}/T_{\text{hot}})$, in which T_{cold} and T_{hot} are the temperatures in Kelvin. T_{cold} and T_{hot} are the temperatures between which the heat engine operates, i.e., the temperatures between which heat flow takes place. Carnot's observation brought to light the fundamental irreversibility in the conversion of mechanical energy to heat. Carnot's work led Rudolph Clausius to formulate the concept of entropy and Second Law of Thermodynamics, which established the fundamental irreversibility of all natural processes.

Entropy. The irreversibility that Carnot discovered in his study of heat engines led to the formulation of the concept of entropy by Rudolph Clausius. The formalism he developed showed that entropy is a state function, i.e., an objectively measurable entropy, S , could be associated with every system in equilibrium. The entropy of system depends on its current state and not on the manner in which the state was reached. The entropy of a system is independent of its history. Like energy, entropy is expressed as a function of

the variables, such as temperature, volume, and chemical composition that specify the state of a system. However, in the classical formalism of Clausius, when a system's state changes from one equilibrium state to another, the changes in the entropy of a system can only be computed for an idealized reversible process. A reversible process takes place at an infinitesimal rate, such that entire evolution can be reversed returning the system and the rest of the universe exactly to their original state. For such a process, the change in entropy is:

$$dS = dQ/T \quad (1)$$

in which dQ is the heat exchanged by the system and T is its temperature. Natural processes, however, are not reversible and they occur at a finite rate, not at an infinitesimal rate. For such processes, Clausius gave the inequality:

$$dS \geq dQ/T \quad (2)$$

This inequality implies that the entropy can only increase or, in the case of idealized reversible process, remain unchanged, but never decrease. Thus, the statement of the Second Law: *Natural processes increase the entropy of the universe*. The formalism gains its power and applicability because changes in entropy between two equilibrium states depend only on the initial and final states, and not on the manner in which the change from the initial to the final state took place. Thus, the changes in entropy due to irreversible processes can be computed using idealized reversible processes for which we have the equality (Eq. 1). It is tacitly assumed that any irreversible transformation of state from one equilibrium state to another can also be achieved through a reversible process for which $dS = dQ/T$.

Thermodynamic Systems. To understand the implications of the laws of thermodynamics, it is convenient to classify systems into *isolated*, *closed*, and *open* systems. *Isolated systems* do not exchange any matter or energy with their environment. In such systems, the entropy reaches its maximum possible value. The rate at which entropy will reach its maximum value in

an isolated system is not predicted by the second law, but that the processes within the system will monotonously increase the entropy until it reaches its maximum value is its prediction. When the system reaches its maximum entropy, it is in a state of equilibrium. *Closed systems* exchange energy with their environment in the form of heat and mechanical work, but they do not exchange matter. Systems whose temperature and volume are maintained constant also reach the state of equilibrium. In doing so, they minimize a quantity called Helmholtz free energy or simply Helmholtz energy, denoted by F . If U is the total energy of the system, Helmholtz energy $F = U - TS$, in which T is the system's temperature and S is its entropy. Similarly, if the pressure and temperature of a system are maintained constant, the system's evolution minimizes a quantity termed Gibbs free energy or simply Gibbs energy, denoted by G . The Gibbs energy $G = U - TS + PV$, in which P is the system's pressure and V its volume. The minimization of Helmholtz and Gibbs energies are a direct consequence of the second law. Gibbs energy is much used in chemical thermodynamics and biology. Similarly, depending on the constraints on the system, other quantities reach their minimum value. Such quantities are sometime referred to as *thermodynamic potentials*. Closed systems may or may not reach equilibrium. For example, if one part of a system is heated while another is cooled, there will be a continuous flow of heat through the system which keeps it from reaching a state of equilibrium. The state of equilibrium is characterized by uniformity of temperature throughout the system in which there is no flow of heat. *Open systems* are those that exchange both energy and matter with its exterior. Such systems are generally maintained in a nonequilibrium state through the flow of energy and matter. As will be described below, under appropriate conditions, such systems spontaneously make transitions to states that are "organized" with more structure than equilibrium systems. Living systems are examples of systems that maintain their structure through continuous exchange of matter and energy with their environment.

Twentieth Century Thermodynamics Formalism. Though the wide range of applications and usefulness of classical thermodynamics are beyond any question, its limitations are quite clear in its formalism. As expressed in equation (Eq. 1) the change in entropy, $dS = dQ/T$, can be calculated only for reversible processes. For irreversible processes, we only have an inequality: $dS \geq dQ/T$. The formalism does not have a way to calculate the changes in entropy for an irreversible process. So it confines itself to calculating changes in entropy between the “initial” and “final” states of a transformation by constructing a reversible process that connects the same states. Consequently, in this formalism, entropy has no direct link to irreversible processes that produce the entropy that is computed. Classical thermodynamics is thus a *theory of thermodynamic states*; irreversible processes are not a part of the theory. The processes for which entropy changes can be computed are idealized, infinitely slow reversible processes. As a result, the theory does not consider rates of changes of thermodynamic quantities. In short, there is no time in the theory. To relate entropy to irreversible processes and convert inequality (Eq. 2) to an equality, we need to know how entropy is related to irreversible processes that we observe in nature. During the twentieth century, contributions made by Onsager, Prigogine, (both received the Nobel Prize for their contributions to thermodynamics) and others, thermodynamics became a theory that is capable of describing irreversible processes. The twentieth century formalism, which we will refer to as *modern thermodynamics*, expresses the changes in entropy of a system, dS , as a sum of two parts (<http://en.wikipedia.org/wiki/Entropy> 2999; Ji 2012; Kondepudi 2008; Kondepudi and Prigogine 1998):

$$dS = d_e S + d_i S \quad (3)$$

in which $d_e S$ is the change in the entropy of the system due to the exchange of energy and matter with its exterior while $d_i S$ is the change in entropy of the system due to irreversible processes that take place within the system. $d_e S$ can be positive

or negative. For instance, in a closed system which exchanges heat, $d_e S = dQ/T$, depending on whether the system is receiving heat or releasing heat, $d_e S$ is positive or negative, respectively. The second term, $d_i S$, relates entropy to irreversible processes. It might be thought as a term that *converts the inequality (Eq. 2) to an equality*. It is expressed in terms of *thermodynamic forces*, F_k and *thermodynamic flows* J_k (the subscripts identify different forces and corresponding flows). Each irreversible process is associated with a thermodynamic force and a thermodynamic flow. Thermodynamic forces drive thermodynamic flows. For example, a gradient of temperature is the thermodynamic force that drives the flow of heat. The change in entropy due to irreversible processes, in a time interval dt , is expressed as:

$$d_i S = (F_k J_k) dt \geq 0, \text{ or } d_i S/dt = F_k J_k \geq 0 \quad (4)$$

That is, the product of a force and flow is the rate at which entropy is produced by that processes. When several forces and flows are at work, $d_i S/dt$, the rate of entropy production, is the sum of all the force-flow products. In chemical systems, the thermodynamic force that drives chemical reactions is called Affinity, a quantity introduced by De Donder (Kondepudi and Prigogine 1998). In this formalism, the second law is stated as:

$$d_i S \geq 0. \quad (5)$$

That is, all irreversible processes increase entropy. All processes in nature are irreversible and take place at a nonzero, finite rate. *Thus, the second law states that every natural process increases entropy.* However, the entropy of a given system need not increase. In isolated systems, $d_e S = 0$; the changes in entropy are entirely due to processes within the system, $d_i S$, and they are always positive, i.e., the entropy of an isolated system can only increase. When the system reaches equilibrium, $d_i S = 0$; there are no processes taking place in the system. Everything in the system is static and the temperature is

uniform. In closed and open systems, $d_e S$ could be positive or negative (sometimes called “negentropy” if it is negative) but the entropy produced by the processes within the system $d_i S \geq 0$, in accordance with the second law. The change in entropy of a system, $dS = d_e S + d_i S$, can be negative if $d_e S$ is negative and sufficiently large in magnitude to overcome the positive contribution of $d_i S$. This is what happens in living cells whose entropy can decrease. Such a decrease in entropy of a system is not in any way in contradiction with the second law which mandates $d_i S \geq 0$.

The Dual Role of Irreversible Processes. Twentieth century thermodynamics brought to light an important aspect of nature: *self-organization*. The inexorable evolution to equilibrium has often been talked about as evolution toward “disorder.” The association of the concept of entropy to “disorder” is unfortunate and has led to much confusion. It had misled people to think that the second law implied that a system could not spontaneously evolve to an ordered state in which its entropy decreases. All this changed, however, when it was discovered in the early part of twentieth century that when a system is far from equilibrium, it can spontaneously become ordered. One of the first and much studied system is the Belousov-Zhabotinsky (BZ) reaction in which the concentrations of the reactants oscillate periodically like a clock. Under other conditions, the same system generates propagating chemical concentration waves (Nicolis and Prigogine 1977). These and other systems that were discovered and studied subsequently revealed an important aspect of irreversible processes (Nicolis and Prigogine 1977): their *dual role* as both *creators* and *destroyers* of order. When a system is close to thermodynamic equilibrium and evolving toward it, irreversible processes tend to reduce order. For example, when the BZ system is close to thermodynamic equilibrium, the concentrations change monotonically toward their equilibrium value at which the entire system becomes homogenous and static. This monotonic behavior has been associated with the inexorable increase in entropy, hence the second law. But the correct

interpretation of the second law is that when chemical reactions take place, the entropy increases. When the BZ system is sufficiently far from equilibrium, however, the concentrations begin to oscillate spontaneously, like an organized clock. The non-monotonic oscillatory change in concentrations is perfectly consistent with the second law because it is the consequence of irreversible chemical reactions which increase the entropy. The same irreversible chemical processes lead to both monotonic concentration changes toward static equilibrium state and the dynamic, “organized” oscillatory changes in concentration. *They destroy order when close to an equilibrium state but create order when a system is far from equilibrium.* The realization of the role of irreversible processes (that dissipate free energy) while creating ordered states has given rise to the term *Dissipative Structures*, structures we see in nature that are generated and maintained by entropy producing dissipative processes. This term was coined by Ilya Prigogine and represents an important concept in understanding *order* and *disorder* in nature (Nicolis and Prigogine 1977). *Dissipative structures* are often used synonymously with “self-organizing chemical reaction diffusion systems” (Nicolis and Prigogine 1977). The Belousov-Zhabotinsky reaction is a widely recognized example of self-organization; the Bernard convection cells provide another type of example (Ji 2012, p. 17).

Thermodynamic Entropy versus Information-Theoretic Entropy. The term “entropy” was coined by Rudolf Clausius in 1865 as a *thermodynamic state function*. In 1948, upon the recommendation of von Neumann, Shannon employed the same term to refer to H , a mathematical function (later known as the Shannon entropy) that he invented to quantify the average amount in bits of the *information* transmitted by a message. It had no connection to the physical entropy that originated in Carnot-Clausius formulation of the concept. Furthermore, Shannon’s formalism uses the term “information” in a very narrow sense. The main success of Shannon’s concept is in coding theory. Shannon’s H is a measure of how much a message

coded in bits can be compressed by appropriately coding it. The association of Shannon's H with "entropy" is due to similar mathematical expression used to define the entropy of thermodynamic system in terms of the micro-states of the system. To overcome terminological confusions and facilitate logical analysis of the theoretical relation between the *thermodynamic entropy* and *information-theoretic entropy*, it was suggested in (Ji 2012, pp. 97–101) that the former be referred to as the *Boltzmann-Clausius entropy* (designated as S_{BC}) and the latter as the *Shannon entropy* (S_S) and that S_{BC} be viewed as a subset of S_S . According to these suggestions, there are many different kinds of S_S , of which only S_{BC} is subject to the Second Law of thermodynamics. In contrast, Jaynes and his followers, for example, assert that S_S and S_{BC} are identical within proportionality constant, implying that S_S also obeys the Second Law of thermodynamics which is thought to be false.

Self-identification

Science

Chemical thermodynamics is a subdiscipline of thermodynamics, one of the major branches of natural sciences which include astronomy, Newtonian mechanics, optics, electromagnetism, relativity theory, quantum mechanics, and statistical mechanics. All these disciplines represent systematic knowledge about the universe that has been acquired through observations/experimentations, analysis of data utilizing mathematical and computational methods, and testing logically inferred predictions.

Characteristics

Chemical thermodynamics is the study of the changes in heat production or absorption and structural organization and disorganization that result from chemical transformations in macroscopic and microscopic scales. This contrasts, for example, with mechanics whose main focus is the study of the motions and their causes of material

objects (also called particles), both macroscopic and microscopic, in space and time.

Relevance to Science and Religion

Since chemical thermodynamics is one of the best established branches of natural sciences, it should shed important light on the relation between science and religion. For example, the fact that both organisms and abiotic objects such as rocks and stars are constituted of the same set of chemical elements and subject to the same set of thermodynamic principles (e.g., the First and the Second Laws) may have profound consequences for the basic tenets of many religions in the world. Although both organisms and abiotic systems are built out of the same building blocks, their properties and behaviors are dramatically different because the way these building blocks are organized in space and time is different.

Sources of Authority

The authority of chemical thermodynamics as a subdiscipline of thermodynamics derives from the fact that the laws of thermodynamics have been tested and upheld by experiments without any exception so far, since the late eighteenth century.

Ethical Principles

The principle of honesty and objectivity in accepting the results of experiments as they present themselves to us is paramount in all scientific activities, irrespective of whether or not the experimental data fit our theoretical conjectures.

Key Values

The principles and accumulated knowledge of chemical thermodynamics are essential for scientists and engineers to explain and understand their experimental data about material transformations

in and around us, which is a prerequisite for solving practical problems in industry and biomedical sciences.

Conceptualization

Nature/World

It is common among chemical thermodynamicists to accept the model of nature and the universe formulated on the basis of astrophysical observations in the form of the Big Bang theory.

Human Being

Human being or *Homo sapiens* is thought to have originated on this planet about 2 million years ago in Africa and spread around the world thereafter. Analysis of fossils gathered in Africa shows that *Homo sapiens* has evolved from the first living systems that originated on this planet some 3–4 billion years ago through spontaneous generation of self-reproducing chemical reactions-diffusion systems, probably driven by thermal gradient on the earth surface or deep in the ocean floor.

Life and Death

There are now sufficient chemical and computational evidence to indicate that life could have originated on this planet from primordial pools of ordinary chemical compounds subject to temperature gradient some 3–4 billion years ago. Some simple aspects of life, which is astronomically complex phenomenon, have been and is being successfully reproduced in laboratories around the world.

Reality

Chemical thermodynamicists tend to view reality as something that exists out there objectively and independently of the observer and that the regularities embedded in reality can be uncovered through experiments, logical analysis of data, and hypothesis testing.

Knowledge

A system of organized information that can be applied to solving practical problems.

Truth

A statement or proposition that has been formulated based on logic, experimental data, and daily life experiences.

Perception

The sum total of the stimuli that enters our consciousness, leading to some registered traces in our nervous system.

Time

A physical parameter that increases unidirectionally just as the entropy of an isolated system does.

Consciousness

The property of our nervous system that is aware of its surrounding and its own activity, i.e., self-aware.

Rationality/Reason

The ability of our mind to carry out thought processes in accordance with a set of logical rules as well as natural laws.

Mystery

Although much has been learned about the laws and principles underlying chemical transformations in abiotic systems, there still remain many mysteries in chemical thermodynamics, especially when applied to living processes. For example, we all know that life cannot exist without chemical reactions (e.g., eating food) and yet the molecular and submolecular mechanisms that couple chemical reactions to even the simplest of living processes, e.g., muscle contraction or active transport, are still poorly understood.

Relevant Themes

With rise of computers that can manipulate digital sequences, the coding of “information” using digital sequences has resulted in a growing interest in the concept of information. This has led some to identify two major theoretical and philosophical problems facing contemporary thermodynamics – (a) the relation between *entropy* and *information*, and (b) the relation between *energy*

and *information*. The debate on the *entropy-information relation* began in 1948 with the appearance of Shannon's entropy formula for the average amount of information carried by a message, and the discussion of the *energy-information relation* may be said to have begun in 1985 when it was postulated that all living processes are driven by *gnergy*, defined as the complementary union of energy and information (reviewed in Sect. 2.3.2, 4.7 and 4.13 in (Ji 2012)). There are scholars who believe that *entropy* and *information* are basically identical. There are equally numerous scientists and philosophers who support the opposite views. These debates are relevant to the science-religion discourses because science is primarily concerned with energy and matter, while religion has its own perspectives on the origin of everything in our Universe including energy, matter, and information.

Child Surgery

Dietrich von Schweinitz
Pediatric Surgical Clinic, Dr. von Hauner
Children's Hospital, University of Munich,
Muenchen, Germany

Related Terms

[Paediatric surgery](#); [Pediatric surgery](#); [Surgery in childhood](#)

Description

Child surgery deals with all diseases of childhood, for which a surgical operation may contribute to therapy. Childhood comprises all humans from birth to 16 years of age and also includes fetuses and premature newborns ([The European Pediatric Surgeons' Association](#); [The American Pediatric Surgical Association](#); [World Federation of Associations of Pediatric Surgeons](#)). While child surgery encloses diseases of all organs of the body and thus is the historical root of the discipline ► [pediatric surgery](#), the latter nowadays concentrates in most countries on diseases of the inner organs and skeletomuscular system (Ashcraft et al. 2005; Oldham et al. 2005). Especially surgery of the heart, the eyes, the ears, and the brain concerning specialized operations in children have recently become subspecialties of the organ surgery specialties. Because of the relative rarity of many surgical diseases of childhood, pediatric surgery is more and more concentrated to large children's hospitals and university clinics.

Self-Identification

Science

Pediatric surgery deals with the treatment as well as research of diseases of humans during the period of growth and differentiation, that is,

fetuses to approximately 16 years of age. Important aspects are the normal physiology of growing organs and tissues, as well as the pathophysiology of abnormal developments and resulting malformations. Furthermore, surgically relevant acquired diseases of childhood caused by infections and inflammation, trauma and neoplastic (tumor) growth are subject of research and treatment in pediatric surgery.

In research, pediatric surgery is active in performing (1) basic biological investigations and (2) clinical studies. Here, methods and techniques of cellular biology, molecular biology, genetics, physiology, anatomy, physics, chemistry, microbiology, biology, mathematics and statistics are applied according to the rules of these natural science disciplines. For clinical research single or multicenter randomized or nonrandomized patient studies are used according to the rules of good clinical practice in order to develop evidence-based guidelines for treatment (von Schweinitz and Ure 2009).

In clinical practice, pediatric surgery deals with a broad spectrum of malformations and diseases (subspecialties in parenthesis): those of the inner organs of the thorax and the abdomen (pediatric visceral surgery), of the urogenital system (pediatric urology), traumatic alterations of the skeletomuscular system (pediatric traumatology), traumata and malformations of the spine and the brain (pediatric neurosurgery), malformations in the newborn period (neonatal surgery), and – at this time still mostly experimental – of the fetus (fetal surgery). For diagnostics in pediatric surgery, all modern techniques of clinical investigation, laboratory, and radiology are applied modified to the needs of children. For treatment, pediatric surgery utilizes all modalities of surgery, drug therapy, physical therapy, and psychology used also in adults but modified to the needs of the individual age of the patients (Ashcraft et al. 2005; Oldham et al. 2005; von Schweinitz and Ure 2009). In research and clinical practice, pediatric surgery is a close partner discipline to all subspecialties of interne child medicine, that is, pediatrics.

Characteristics

Pediatric surgery is one specialty of human medicine. It is distinctive to other medical disciplines in that it is concerned with disorders of fetuses, children, and adolescents with a surgical relevance, that is, may need a surgical operation. Therefore, the special interest lies on the biology, diagnosis, and treatment of these diseases and malformations.

Relevance to Science and Religion

Because of the many relationships the developing human individual is bound to and the many influences he or she is subject to, pediatric surgery is interested in many scholarly areas. This accounts for all disciplines of human biology, as far as they are dealing with the development of humans and their malformations and diseases, also all specialties concerned with the body, mind, and soul of children and adolescents, but also with scholarly areas engaged in the living and welfare of families, education, sociology, culture, and politics including national and international conflicts (i.e., pediatric traumatology and war damages), finally ethics and religions.

Sources of Authority

Historically, the first authorities in the developing discipline of pediatric surgery were surgeons who realized that the treatment of children with malformations or diseases need specially trained physicians as well as a clinical setting adapted to the needs of children. In the nineteenth century, first departments of pediatric surgery were established in Boston – USA, Paris – France, London – UK, Munich – Germany, and other European countries. Today, authorities for pediatric surgery and its subspecialties exist worldwide. These usually have published handbooks (some see reference list) and are organized in national and international scientific pediatric surgical organizations (see reference list).

Important periodicals are the Journal of Pediatric Surgery, the European Journal of Pediatric Surgery, and Pediatric Surgery International.

Ethical Principles

As a medical discipline, Pediatric Surgery throughout the world acknowledges and is guided by the Hippocratic Oath and the rules of the Declaration of Helsinki of 1971. Because fetuses, newborns, and children are not able to give informed consent as adults, a special concern for the welfare of the individual patient in clinical practice and research is mandatory for pediatric surgeons.

Key Values

The key values of Pediatric Surgery are:

1. The optimal treatment of malformations and acquired diseases of the growing human being of all age groups,
2. The care of these patients in the clinical setting and at their home,
3. To undertake research to better understand the causes, pathophysiology, diagnostics, and possible treatment of these malformations and diseases,
4. To teach medical students and physicians all aspects of this discipline.

Conceptualization

Nature/World

Nature and its rules and interactions are the basis of life and thus also of the human body, its organs and tissues, its cells and its development, growth and differentiation. The world comprises of the materials of all planets and the interspersed space of the universe as well as all aspects of human mind and possible other intelligences unknown to us.

Human Being

The human being is a product of nature with a body including a highly developed brain, giving

the human being the possibility of feeling and abstract thinking, of philosophical and religious conceptualization. The body as well as the mind are subject to development from one cell at the beginning pregnancy.

Life and Death

Life is the presence of functions of biological systems including reproduction, growth, and differentiation. Death is the termination and absence of such functions.

Reality

Reality is understood as the materialistic world as well as actions and products of minds, which can be sensed by the individual human being.

Knowledge

Knowledge is the accumulation of experiences, facts, ideas by biological systems including the human being as well as by physical systems as books, electronic devices, and others.

Truth

Truth is defined as the realities and ideas proven by multiple experiences of human beings or laws of nature, which both are thought to have universal character.

Perception

Perception is explained as the conscious sensations and experiences of all aspects of the physical world of a human being in dependency of health and disease, the momentary situation, and the developmental stage.

Time

Time is a physical category of chronically ongoing processes in the material world, which can be perceived by human beings and objectively measured, implementing aging of biological systems.

Consciousness

Consciousness is understood as the status of the human mind, which enables the individual to perception, mental workup, active reaction, and storage of external influences.

Rationality/Reason

These are thought to be the ability of the human mind to explain, to deal with, and to react to perceptions, feelings, and other influences using logical thoughts. This is dependent on mental health status as well as on the stage of mental development during childhood.

Mystery

Mysteries are perceptions, feelings, and other influences, which cannot be explained rationally by an individual. This is dependent on mental health status and mental development, but also on experiences, culture, religion, and education of an individual and/or group of human beings.

Relevant Themes

The most relevant issues of Pediatric Surgery are not only cure from surgical diseases and malformations of the growing human being, but furthermore the well-being of children in all aspects of life in order to facilitate their development to healthy, mentally intact, and responsible adults ([The European Pediatric Surgeons' Association](#); [The American Pediatric Surgical Association](#); [World Federation of Associations of Pediatric Surgeons](#)).

Chiliastic

Hans Schwarz

Institute of Protestant Theology, University of Regensburg, Regensburg, Germany

The term is derived from the Greek *chilioi*, meaning a thousand (years). The idea was widely held that one thousand years after Christ, Christ will return and a new age will dawn. This led to the expectation of a thousand years' rule of Christ. This idea was secularized by Marx and Engels and later by the Nazi ideology into a secular Thousand Years' Reich. It can also mean the triumphant and overzealous attitude to bring about paradisiacal conditions through one's own efforts.

Christian Cosmology

Anna Ijjas

Harvard University, Cambridge, MA, USA

Related Terms

[Big bang cosmology](#); [Creatio continua](#); [Creatio ex nihilo](#); [Creation](#); [Multiverse](#); [Natural evil](#)

Cosmology is the scientific study of the Universe *as a whole*, seeking to understand its origin, evolution, and structure. Until modern times, there was no difference between scientific and religious cosmologies; scientific cosmology was at the same time religious cosmology. Its major concern was to strengthen and unfold the biblical idea of creation as depicted in the book of Genesis, by invoking empirical insights about the world. Simultaneously, in introducing God as the ultimate cause of natural processes, one could provide an explanation for all empirical facts involved. Many contemporary theologians follow the ancient thought, that is, how to embed scientific findings the biblical message and the core Christian doctrines – the product of centuries-old theological reflection based on the first chapter of Genesis. However, after science became decoupled from theology, the competences have been redefined. Given the (methodological) autonomy of science, contemporary Christian cosmology seems to be best understood as theological reflection about physical cosmologies in terms of a *coherence test*, which means, in reflecting scientific cosmologies, theologians see it as their task to integrate new scientific insights into the traditional doctrines of Christianity as well as to reinterpret (or reformulate) these doctrines insofar as that is necessary for the integration of scientific theories (cf. Barbour 2000). Consequently, while physical cosmology seeks to understand the origin, evolution, and structure of the Universe, Christian cosmology seeks to integrate the results of the scientific endeavor into the core Christian doctrines of divine creation.

The Origin of the Universe

The traditional Christian doctrine – as formulated, for example, by Saint Augustine – states that in the beginning God created the Universe out of nothing (*creatio ex nihilo*), which means, directly or indirectly, *everything* owes its existence to God, or to put it another way, God is the ultimate cause of the Universe (cf. Craig and Copan 2004).

According to the classic understanding of Genesis 1:1, *creatio ex nihilo* entails that the Universe had a *temporal beginning*. However, following the tradition of Boethius, Anselm, and Aquinas, divine perfection requires that God exists outside of time, is timeless. Understanding the world as temporal while God as atemporal became one of the major problems for philosophers of religion. Hence, some modern theological concepts assert that God is genuinely in time even if God created a world *ex nihilo* (*open theism*) or formed an eternally existing “stuff” (*process theology*).

Understanding God as Temporal Cause of the Universe

Traditionally, the question if God can be considered as the temporal cause of the Universe arose in the context of the so-called *kalām cosmological argument*, which was introduced by medieval Arabic theologians – therefore also the name *kalām* that was applied to the argumentative theism employed in defense of Islamic orthodoxy beginning in the ninth century. More recently, the *kalām* argument was revived and defended by American philosopher William Lane Craig (cf. Craig and Smith 1995). The *kalām* argument infers from the existence of the universe to God’s existence by proving that the universe is in need of a temporal cause, in reconciling the traditional doctrine of *creatio ex nihilo* with physical cosmology. The question is, thus, if the Universe is in need of a temporal cause?

Contemporary proponents of the traditional understanding appeal to two different scientific developments to support the doctrine of *creatio ex nihilo*, namely, mathematics of infinity and the big bang theory. Allegedly, the mathematics of infinity could provide an a priori argument for a finite-age universe insofar as a (temporally) infinite universe implies the existence of an actual infinite. Thereby, an actual infinite represents a timeless totality that neither decreases nor increases in the number of members it contains, whereas a potential infinite is a process that comes closer and closer to infinity but never reaches it – a distinction originally introduced by Aristotle to resolve Zeno’s paradox

(cf. Bostock 1973). By referring, for example, to a hotel as an actual infinite which can accommodate a new guest even if its fully occupied (called Hilbert's Hotel, cf. Gamow 1989), proponents of the *a priori* argument from the mathematics of infinity argue that the existence of an actual infinite seems intuitively absurd, which leads them to the conclusion that an absolute infinite cannot exist. That is to say, with regard to its temporal extension, the Universe represents a potential but no actual infinite. However, this *a priori* argument counts as a fairly weak one, mainly because it seems to tell us more about our cognitive capacities than about reality itself. For it is at least not evident that things we cannot imagine (or consider to be an absurdity) cannot exist. If that were the case, general relativity or quantum physics should also be regarded as absurdities, which surely is not the case. In conclusion, mathematics of infinity is not very helpful, insofar as it is impossible to prove by way of *a priori* considerations that the Universe is a potential and not an actual infinite.

In order to reconcile the traditional understanding of *creatio ex nihilo* with modern science, it is perhaps more promising to appeal to the standard big bang theory (Cf. article on ► [cosmology](#) by Kenneth R. Lang in this volume). As a matter of fact, the classic interpretation of the fact that the universe (including space-time) arose out of a singularity, that is, out of an original state of infinite density and temperature, and no size (i.e., the universe had a temporal beginning), was mostly welcomed among theologians. Indeed, the big bang theory suggests that physical cosmology directly supports the core theistic belief in *creatio ex nihilo*.

However, the classic interpretation of big bang theory is not fully accepted by all physicists. The possibility that a physical theory could prove that science has reached its boundaries appears dissatisfying to most physicists. Therefore, various alternative theories were developed. Such an alternative theory, or rather bundle of theories, is the theory of oscillating or cyclic universes as presented by Paul Steinhardt, Neil Turok, or Roger Penrose, stating that our big bang is but one in a series of countless "bangs": The universe

goes through repetitive cycles of expansion and contraction; a new big bang occurs when the antecedent big bang universe reached its end phase, that is, after it arrived at a completely homogeneous, highly dense, and extremely hot state (Big Crunch). Another possibility to avoid a temporal beginning provides the theory of inflation, first suggested by MIT-physicist Alan Guth in 1981. Inflation posits a stage of rapid expansion in the very early universe, originating in a quantum vacuum state. Thus in the framework of inflationary cosmology, the universe does not need to have a temporal beginning insofar as the quantum vacuum might be eternal. While cyclic universe cosmologies are often considered as too speculative, the theory of inflation is widely regarded as a necessary complement of standard big bang cosmology, filling the explanatory gaps of the latter, the striking large-scale homogeneity of our universe, and the origin of structure. Yet, even if inflationary theory does not necessarily rule out a temporal beginning insofar as the quantum vacuum state does not need to be eternal, the classic interpretation of standard cosmology is not compelling. Indeed, the fact that the field equations lead to a singularity (when tracked back in time) could simply mean that general relativity does not apply to the epoch before inflation, so that we are in need of new physics to explain that era.

To sum up, if the classic interpretation of standard big bang cosmology turns out to be the only proper understanding of the theory, the traditional understanding of *creatio ex nihilo* can be considered compatible with science. However, until there are serious alternative theories (or interpretations), the empirical basis of the *creatio ex nihilo* doctrine (understood in terms of a temporal beginning) remains questionable.

Not only scientists question the assumption of a temporal beginning for the Universe, also theologians have their doubts. It has often been argued that a proper interpretation of the Bible does not imply a temporal beginning. Rather, the opening verses of Genesis start with depicting a watery chaos: "The earth was without form and void, and darkness was upon the face of the deep and the spirit of God was moving over the

face of the waters.” In fact, church historians have recently pointed out that the idea of *creatio ex nihilo* was first formulated in the second century, as a response to the Gnosis teaching that matter is evil. Accordingly, the doctrine of *creatio ex nihilo* had a twofold aim. Firstly, it asserted that God is the source of matter as well as form against claims that a preexisting matter could limit divine power. Secondly, it asserted God’s transcendence against the idea that the world was an emanation of God, made of the divine substance and sharing its characteristics. Indeed, the interpretation of *creatio ex nihilo* in terms of a temporal beginning was first elaborated by Augustine and cannot, therefore, be regarded important for the self-definition of the early church. Particularly, scientist-theologians Ian Barbour and John Polkinghorne argued against conceiving of God as a temporal cause of the Universe (Barbour 2000 and Polkinghorne 2006). They hold that such a view rests upon a theological misunderstanding of Genesis that – sooner or later – becomes entangled in contradictions with science. Instead, they emphasized that we should think of divine creation as a “fundamental and enduring relationship” between the faithful God and the world (*creatio continua*). As a proper interpretation of Genesis 1:1, they suggested to conceive of God, the Creator, as the nontemporal or metaphysical cause of the Universe (Cf. article on ► [divine creativity](#) by Gloria Shaab and the article on ► [creator – co-creator](#) by Barbara Ann Strassberg in this volume).

God as Metaphysical Cause of the Universe

The common strategy to argue for God as the metaphysical cause of the Universe operates by distinguishing different kinds of modality, contingency, and necessity.

That God is conceived of as a *necessary being* is known as the *sovereignty-aseity intuition* (Plantinga 1980, Davidson 1999). Thereby, the idea is the following: Necessarily, *x* depends on *y* for its existence iff *y* were not to exist, neither would *x*. In other words, if the number four depends on God for its existence, then the truth of four exists depends counterfactually on the

truth of the proposition God exists, if God exists were false, then four exists would be false (Matthew Davidson 1999). In turn, this means that four is a *contingent being*, that is, dependent upon the existence of another being (be it contingent also or necessary). Another approach to understanding necessary and contingent beings comes from modal or metaphysical logics. Understood as such, a necessary being exists in all possible worlds, while there is at least one possible world in which a contingent being does not exist.

By applying this distinction, proponents of the *metaphysical argument* believe to have shown that even if the Universe has no temporal beginning, it is contingent and thus depends on something else. Here an additional premise is assumed, however, according to which a contingent being always has a cause of its existence – this assumption is usually called the *principle of sufficient reason*. In fact, it is this principle that calls for a necessary being to be the ultimate cause of the Universe. The final goal of the argument is then to show that this necessary being can only be God.

To sum up, if it turns out that standard big bang theory implies a temporal beginning of the Universe, the doctrine of *creatio ex nihilo* can be considered valid in its classic interpretation; on the other hand, regardless whether science predicts a temporal beginning of the Universe, God can be considered as the ultimate metaphysical (or nontemporal) cause of the Universe, responsible for its origin and for sustaining it (as understood in terms of *creatio continua*). However, compatibility does not imply exclusivity. That is to say, the scientific picture clearly allows for both a theistic explanation and a naturalistic interpretation.

The Evolution and Structure of the Universe

The more philosophical question whether God can be conceived of as the ultimate cause of the Universe is closely related to the problem of explaining the evolution and structure of the Universe. Suppose that an ultimate metaphysical

cause (which might be a necessary being) is needed to count for the existence of the Universe. However, whether this ultimate cause is indeed God as God is understood in classical theism, depends on whether the Universe *as it is* can be ascribed to a morally perfect, omniscient, and omnipotent being. Furthermore, according to Immanuel Kant, it is not evident that the necessary being (*ens necessarium*) is the absolute (or mostly real) being (*ens realissimum*). Nor can the biblical account of divine creation be reduced to the belief that God is the ultimate cause of the Universe (Cf. further article on ► [divine action](#)).

In fact, to reinforce naturalistic interpretations of big bang cosmology, it has often been claimed that, though the Universe could be contingent, God cannot be considered its ultimate cause, insofar as characteristic features of the Universe are incompatible with the Christian image of a faithful God. In this context, particularly the problem of evil (cf. further article ► [evil, problem of](#), by Thomas Anderberg in this volume) has been often cited as an argument against divine creation – whether in terms of *creatio ex nihilo* or in terms of *creatio continua*.

The Fine-Tuning Argument

Contemporary cosmologists study the laws governing the entire Universe and hence focus (primarily) on physical laws describing the structure and evolution of the Universe. While so doing, they assume the *cosmological principle*. Usually, the cosmological principle says that, “viewed on a sufficiently large scale, the properties of the Universe are the same for all observers” (Keel 2007). This implies that the Universe is homogeneous and isotropic, which means, despite its immense size, the same natural laws apply everywhere in the Universe.

The cosmological principle is regarded empirically extremely well confirmed – the most striking evidence comes, again, from the impressing homogeneity of the cosmic microwave radiation we already discussed above as empirical evidence for an expanding universe. In several theological reflections, it is – unsurprisingly – precisely the cosmological principle by way of which the characteristic traits of the Universe are

linked with the conditions here on Earth, in particular with human life. If the Creator wanted intelligent life to evolve somewhere in the Universe – so the argument runs – the Creator had to establish the laws such that they allow for the evolution of intelligent life. That means, the structure of the entire Universe has to reflect the possibility of intelligent life – even if intelligent life can factually evolve only within a tiny fraction of the entire Universe.

In order to strengthen this somewhat bold idea and to harmonize it with current scientific insights, theologians usually refer to the fact of *fine-tuning*, that is, that both the mathematical form of the laws and the values or constellation of the fundamental parameters which together characterize the structure and evolution of the Universe are such that even minimal deviations from the observed values would have led to massive changes in the physical evolution, possibly ruling out the emergence of intelligent life.

Consider, for example, the mass ratio between proton and neutron: Although their mass difference is only 1.29 MeV ($\sim 0.14\%$), which is vanishingly small, it is nevertheless bigger than the tiny mass of the electron ($\sim 1/1,836$ of the proton mass). However, if the electron were more massive than the mass difference between proton and neutron, free neutrons would be stable and could not decay into a proton-electron-antineutrino triple. As a consequence, most of the protons and electrons in the early Universe would have combined to form neutrons and neutrinos. In such a universe, only neutron stars could have emerged, the emergence of atoms or other chemical elements would not have been possible, not to mention the emergence of life. If instead of changing the mass ratios, we would change the electromagnetic into gravitational force strength ratio of 1,036 by reducing it to, for example, 1,033, the consequence would be that only a short-lived miniature universe could exist. Hence, there would simply be no time for biological evolution. The probability that we find even a few fundamental parameters having the observed ratio to one another, which is necessary for our very existence, appears to be extremely small, and the totality of them together vastly

more so; according to calculations of physicist Lee Smolin, the probability is about one chance in 10^{229} . Recognizing this remarkable coincidence, scientists in the 1960s suggested that it should be considered a physical phenomenon (or explanatory pattern) *sui generis*, which became known as the *anthropic principle* (Tipler and Barrow 1988). This principle is based on observations that the laws of nature and parameters of the Universe necessarily take on values consistent with the conditions for life on Earth.

For theological considerations, the point of anthropic reasoning lies in the *post hoc* character of the argumentation, reducing cosmic fine-tuning to the existence of intelligent life. Even though it is not supposed to be an implication of the scientific argument, in facing the extremely small probability of the observed constellation, anthropic reasoning seems nevertheless to suggest a *teleological interpretation* (cf. Leslie 1989). If the Universe has expected us from the very beginning, assuming the existence of a divine creator appears fairly plausible. By reverse conclusion, the anthropic principle might present an empirical argument for the existence of God. Moreover, it has the potential to refute another empirical argument against the existence of God, namely, the atheistic claim according to which the Darwinian explanation of the origin and evolution of life on Earth in terms of random mutations and natural selection makes the creation hypothesis obsolete. In order for evolutionary processes to occur, the observed fine-tuned parameters, initial conditions, and natural laws are needed. This, in turn, brings God back into play.

Objections

However, the anthropic principle has been largely criticized. The argument is that none of the finely tuned phenomena require human life or some other sort of carbon-based life. Rather, it is said, any form of intelligent life would do (Stenger 2011). In response to criticism, the anthropic principle has recently been redefined in the argument from fine-tuning.

However, the only scientific alternative approach to explaining fine-tuning does not

appear more promising: To solve the fine-tuning problem, scientists have questioned the apparent uniqueness of our Universe by referring to quantum many-worlds or inflationary multiverse scenarios. If our Universe – so the argument runs – is but one among infinitely many other universes, it seems hardly surprising that in one of these universes the observed constellation is realized. For the sake of argument, let us suppose that there are indeed infinitely many universes. What would the existence of such a bundle of universes mean for Christian Cosmology? Consider the following two cases: (1) All universes in the multiverse are described by the same Theory of Everything (2) The universes in the multiverse can be grouped into bundles, which are described by different theories of everything, respectively. In the first case, the problem of fine-tuning is only shifted, insofar as the question still remains open *why* the multiverse is described by the given Theory of Everything, characterized by certain fundamental parameters and a certain mathematical form. In the second case, the fine-tuning argument can be regarded resolved only if all mathematically possible forms are realized. This, however, entails the extension of physical reality over tremendous dimensions, while the only motivation for this is a purely metaphysical one, to provide a naturalistic interpretation of cosmic fine-tuning.

All in all, there is a price to pay when the theistic interpretation of cosmic fine-tuning should be replaced by way of multiverse theories, and in face of the ontological curiosity multiverse theories entail, it is in the final analysis left to the philosophical or theological preferences if one asserts the theological or the naturalistic alternative. Yet, being merely metaphysical assumptions, multiverse theories cannot be considered as a serious objection to a theistic or Christian interpretation of cosmic fine-tuning. Furthermore, if our Universe is not the best of all possible worlds (which seems quite likely), it is even plausible to claim that God created all universes above a certain axiological threshold than to assume that God created only our Universe while neglecting to create any better ones. That is to say, it seems possible that neither just one

universe exists solitarily nor all possible universes exist simultaneously, but God created a subset of all logically possible universes, whether interconnected, whether causally inert. Clearly, advancing the possibility of creating a world that is a multiverse, the most important question is why God chose the actual world, why God preferred one possible world to an enormous number of others. In other words, for a multiverse theory to be successful, it is necessary to identify *world-good-making properties*, that is, conditions for a world to be worthy of creating. Indeed, developing a comprehensive theory of theistic multiverse is today an emerging research field in both theology and philosophy of religion (Kraay 2012). In the near future, we can hope for interesting results.

Concluding Remarks

Christian Cosmology has always been conceived of as the endeavor to reconcile the biblical message of creation with the actual scientific insights concerning the origin, structure, and evolution of the entire Universe. Understood as theological reflection about physical cosmologies from a Christian point of view, Christian cosmology is not about direct inference from facts about the world to knowledge of ultimate reality but can be a powerful tool to harmonize the biblical idea of creation with contemporary culture. Therefore, promoting the dialogue between scientific and Christian cosmologies appears inevitable to make the biblical message understandable in modern societies. At the same time, Christian belief can provide an overall context for scientific cosmologies, demonstrating that the mutual interaction of science and religion can indeed arrive at a comprehensive and coherent worldview.

Christian Ethics

Kevin Jung

School of Divinity, Wake Forest University,
Winston Salem, NC, USA

Description

Christian ethics is an enormously rich and diverse field of study that investigates a wide range of ethical topics and issues using moral resources often drawn from but not necessarily limited to the Christian tradition. As a critical reflection on Christian morality, Christian ethics seeks to answer hard questions about the sources and criteria of moral knowledge as well as the normative claims made by Christian morality in response to various ethical issues and problems. Despite the fact that the phrase “Christian morality” may seem to suggest otherwise, all Christians of course do not hold the same moral views; the Christian moral tradition is more like a huge repository of many divergent ideas, beliefs, and practices born out of distinct Christian communities than a monolithic system. Thus, it should be of no surprise that there are a number of ways in which the study of Christian ethics is done and can be done. So how should we attempt to canvass this vast field in a limited space?

For our purposes, I suggest that we make use of some conceptual distinctions often used by moral philosophers in order to clarify and outline some of the important ideas and schools of Christian ethics.

We can begin by noting a distinction between first-order accounts and second-order accounts of moral reasoning. The former, typically referred to as normative ethics, raises questions about the content of ethical claims, such as the standards of moral judgments and the rules of moral obligation. The latter, often known as metaethics, is concerned with the status and nature of ethical claims. Metaethics seeks, among other things, to answer questions about the nature of moral knowledge and truth as well as the metaphysical status of moral properties. Later in Part two, I will discuss only some of the epistemological issues

in metaethics. The distinction between normative ethics and metaethics should serve us well as we consider a variety of approaches and topics within Christian ethics.

Normative Issues in Christian Ethics

Ethics is commonly defined as the knowledge of right and wrong (as well as good and bad). This short definition, though insufficient to capture all areas of ethics, highlights something important in ordinary moral reasoning: standards of moral judgments. We human beings make moral judgments about the actions and characters of moral agents, which are implicitly or explicitly based on certain moral standards. Though normative ethics has become a highly specialized field within analytic moral philosophy, ethical discourse involving moral standards still largely draws upon the traditional normative theories: psychological egoism, ethical egoism, deontologism, consequentialism, and ► [virtue ethics](#). Our question in this section is whether Christian theologians and ethicists ever appeal to the moral standards proposed by these normative theories.

The short answer to this question is clearly, “yes.” From Christian love ethics to ► [liberation theology](#) and from just war theory to biomedical ethics, the kinds of moral judgments commonly made in Christian ethics cannot avoid using moral norms. Let me illustrate this by focusing on the debate over moral norms from the 1960s to 1980s, during which Christian ethics in Europe and North America was deeply engaged with the criteria of moral norms. Ethical issues such as contraception, abortion, and euthanasia often dominated Christian ethical discourse. Interests in such issues were not accidental; this era saw an unprecedented technological development in medicine that engendered ethical questions about certain reproductive and medical practices, and the debates about these questions eventually became a part of the contemporary social and political landscape.

If there was one book in Christian ethics that created a firestorm during this era of social and cultural upheaval, it was Joseph Fletcher’s *Situation Ethics*. In this book, Fletcher argued that

there are no moral absolutes except love (Fletcher 1966). The basic idea was first the claim that the only legitimate criterion for judging the moral status of an action is whether it can be justified by love, that is, the New Testament notion of ► *agape*, and second, the assertion that love justifies the means to any given end. Alarmed by the denial of moral absolutes and moral laxity in the wider culture and in the church, the Roman Catholic Church began to confront these questions head-on. In his papal encyclical letter *Humanae Vitae*, published in 1968, Pope Paul VI made it clear that direct sterilization, artificial contraception, and abortion (with the exception of therapeutic abortion) are illicit. Paul VI's views on these matters would be reaffirmed later by Pope John Paul II and Pope Benedict XVI. What is important for our purposes is that they all insisted, based on their interpretation of natural law and church tradition, that there are certain acts that are intrinsically evil by virtue of the material means they used, and regardless of the agent's intentions or the consequences of the act. This view is often called "absolute, exceptionless moral norms" and it created a controversy not only among Catholic moral theologians but also among Protestant ethicists. Proportionists, a group of Catholic moral theologians such as Peter Knauer, Joseph Fuchs, Louis Janssens, Richard McCormick, and Bruno Schüller, instead argued that the morality of an act cannot be determined without considering carefully the final end or the intention of the agent (*finis operantis*) and the end of the act (*finis operis*). Briefly, their view is that we may permit the evil effect of our act only if (1) this result is not intended in itself (i.e., the end is indirect) and (2) it is justified by a commensurate reason (i.e., it is proportionate to the morally acceptable intention of the agent within the totality of his act). In contrast, those who hold the absolutist position have accused proportionists of being consequentialists who hold that one may do evil in order that good may come.

We should also note a Protestant ethicist who was particularly interested in the debate about moral norms. Paul Ramsey, a well-known ethicist in the twentieth century, was vehemently opposed

to consequentialism, calling its harmful effects the "wastelands of relativism." Like Fletcher, Ramsey viewed Christian love as central to Christian morality; however, these thinkers could not be farther from one another in terms of how they understood the normative meaning of Christian love. For Ramsey, Christian love, which is grounded in the righteousness of God and Jesus' teaching about the Kingdom of God, has a covenantal character. According to him, Christian love signifies disinterested love for one's neighbor in obedience to the sovereign rule of God. For Ramsey, the point of Christian moral life is not to maximize happiness for oneself or others but to value each human for his or her own sake as the image of God. His ethics is also noteworthy because it regards moral rules as specifiable or revisable in light of certain moral facts relevant to moral cases. On this view, since they impose actual rather than *prima facie* moral duties, alleged exceptions to moral rules are not really *exceptions*, but instead should be considered further specifications of moral rules (Ramsey 1968).

All this clearly indicates that various positions among Christian thinkers involve normative ethical theories. On closer examination, Fletcher's situation ethics is a form of act-utilitarianism (or act-agapism) which uses the principle of utility as the only criterion of morality. In contrast, the official teachings of the Catholic Church advocate a rigid deontologism that allows no exception to moral rules. Catholic proportionists, however, disagree with this official position by offering a version of rule-utilitarianism that holds to the primacy of moral rules in promoting the utility of an action. Ramsey's Protestant ethics offers a moderate deontologism that recognizes the possibility that *prima facie* moral duties can be overridden by other actual moral duties.

Ironically, the fierce debate about moral norms helped other Christian thinkers to shift their focus onto a different kind of moral standards: virtue (Hauerwas 1981; Porter 1995). Since 1980s, there has been a movement against rule-oriented ethics and toward character-oriented ethics. Virtue ethics, of course, is not uniquely a contemporary phenomenon; it is traceable to, among others, the ethics of Aristotle and Aquinas. Yet, the recent resurgence of

virtue ethics is not accidental. On the one hand, it is a critical reaction to modern individualism and the Enlightenment morality that emphasized the role of reason in moral judgment. On the other hand, it is also an effort to reclaim the distinct moral ethos of the Christian community.

Epistemological Issues in Christian Ethics

From the early church to the contemporary church, there have been various claims to religious and moral knowledge. Disagreement between Christian communities makes these claims appear problematic; what a particular Christian community purports to be a true belief is not always the same as what another Christian community holds to be true. Unfortunately, differences in beliefs between distinct Christian communities have often led to social oppression and even political persecution, as seen during the Radical Reformation, the 30 Years War, the English Reformation, and the American Puritan struggle for religious freedom. Sometimes, change of moral beliefs has occurred within the same religious community as a result of such periods of oppression. Consider the history of Christian attitudes toward usury, slavery, and women's suffrage; in these examples, we see a long-standing church tradition changing its course after a long and difficult period of social, political, and religious transformation.

All this should raise a question about how true moral beliefs in a given Christian community can be held justifiedly. Can those who claim to possess knowledge give sufficient grounds for holding their beliefs to be true? Have Christians or Christian communities tried to offer such grounds for justification? In the following, we will consider some commonly cited sources of evidence in Christian ethics.

Scripture

Christians have long depended upon the Bible for moral guidance, and have done so for a good reason: the Bible has been believed to be or to contain the Word of God and, thus, is thought to possess normative authority for the Christian moral life. Of course, assuming that this is true, we can raise an additional question of whether the biblical text is really a good evidential basis for moral knowledge.

Though there are plenty of people who believe that the Bible gives us unambiguous moral truths, it is an undeniable historical fact that, since the early church, the correct interpretation of the Bible has been highly disputed. Christian theologians have long been aware of the difficulty of using the Bible as a moral guide. To mention only a few, St. Clement introduced allegorical method of biblical interpretation in order to avoid literal interpretations of the Bible. St. Augustine rationalized the idea of just war by appealing to the love of one's neighbor. St. Aquinas explained self-defense as a natural right for all, and did so in the face of a long-standing church tradition on the contrary.

Therefore, it should come as no surprise that many contemporary Christian ethicists caution against attempts to declare the Bible as the ultimate authority for Christian ethics or to equate biblical ethics with Christian ethics. For example, arguing that there are many sources of moral reflection for Christians, H. Richard Niebuhr has said that his ethics is "bible-informed," and not "bible-centered" (Niebuhr 1963). Niebuhr's position is just an instance of the more general contemporary move deviating from the use of scriptures as infallible proof of Christian moral claims.

Tradition or Community

Christians often appeal to their tradition or community as the grounds for justifying their moral beliefs. Historically, the Roman Catholic Church has long held that it is the apostolic tradition of the church that gives authority to scripture. In his famous debate with Martin Luther, for instance, John Eck renewed the Catholic doctrine of the authority of tradition over against that of Scripture. In his view, it is the church that had created Scripture and established its canon, and thus, the church has proper authority over Scripture.

In recent years, however, there has been a wider appeal to the Christian community as the grounds for justifying moral beliefs. One important source of influence, in this regard, has been a particular version of Wittgensteinian philosophy, according to which truth is not a property that a statement has when it

corresponds to reality, but rather is merely a function of language. George Lindbeck, known as a representative of the Yale School of “narrative” theology, along with Hans Frei, made it his theological thesis that Christian truth claims should not be understood as propositions that can be known as true or false outside of one’s particular linguistic community or as expressions of individual religious experience, but rather should be viewed as referring to the world only as described by the users of a particular linguistic community (Frei 1974; Lindbeck 1984). Lindbeck held that since the meaning of a linguistic statement is a function of its use, the truth of any given statement is explainable in terms of the linguistic rules accepted and employed by the statement’s users.

Another source of influence is the rejection of universal, objective morality based on foundationalist ► [epistemology](#). Some Christian thinkers complain that Christian ethics has lost its distinct message in the liberal state by trying to make the Christian narrative more palatable and intelligible to those who are not Christians and by adopting the public moral language of the liberal state. Stanley Hauerwas and John Milbank, for instance, claim that because all morality is particular to historical, social, and societal practices there is no such thing as a *universal* morality. According to them, there is no Archimedean point of view from which we can judge the moral beliefs of a particular society other than our own. What this means is that no one outside of the Christian community has the authority or ability to judge the truth of Christian convictions. They submit that only the Christian community can furnish the principal criterion for justifying Christian beliefs, and hold that the intelligibility of theology and ethics derives only from the practices of the church.

Critics of such contextualist theory of justification point out that this kind of Christian ethics is a sectarian theology that divorces the Christian community from the wider world (Gustafson 1985). They also argue that it is a form of moral relativism since the truth of moral beliefs is made relative to particular societies.

Experience

Ever since Latin American liberation theology came to the fore in 1960s, there has been a plethora of new ethical theories that make the particular experience of a certain group of Christians their centerpiece: black liberation theology and ethics, feminist ethics, womanist ethics, Asian liberation theology, postcolonial theology, Latino/Latina ethics, and so on. In this regard, these theologies and ethics employ an inductive approach to moral knowledge, deriving the latter from experience. Despite many differences among these theologies and ethics, there is one important commonality. In a way, they are all distant relatives of the nineteenth century’s liberal theology, which made human experience the most important source of doing theology. In any such experience-based Christian ethics, the experience of a particular group becomes both the source and the criterion of moral knowledge.

Another similarity among these theologies and ethics is that they all seek liberation as their goal. To put this in a simplistic manner, Latin American liberation theology, for instance, focuses on the liberation of the poor and those who are politically and economically oppressed in Latin America; feminist ethics seeks to emancipate women from patriarchy and gender-based inequality; womanist ethics seeks to liberate black women from their oppressive social, cultural, and economic systems. However, there is a widely shared view among contemporary liberationists that all who are oppressed are connected with each other not only through their shared suffering but also the oppressive systems themselves. In this regard, there is a growing tendency among various groups of liberationists to collaborate and join the resistance movement. One such example is an alliance between feminists and environmentalists, both of whom are interested in addressing the degradation of nature, which many feminists believe mirrors the oppression of women. Thus, ecofeminists argue that the liberation of women can also lead to the liberation of nature and vice versa (Ruether 2005). Needless to say, there are many divergent views among liberationists, and this makes a fair assessment of their ethics very difficult. Having said this, there

are two main difficulties with experience-based ethics. First, they are prone to identity-dependent ethical and political discourse where members of certain social, cultural, or religious groups are often overly sensitive to external criticisms by appeal to their shared experiences, and second, their attempts to justify values such as equality and individual liberty may be self-defeating, since they also deny the very existence of universal human values based on shared human experience.

Reason

Historically speaking, reason has held a venerable position in Christian ethics. Many early church fathers tried to defend the Christian faith in the time of persecution, emphasizing the harmony of reason and faith. In the Middle Ages, Aquinas continued this emphasis by synthesizing reason and revelation in his twofold theory of happiness. Bishop Butler, John Wesley, and Jonathan Edwards all acknowledged that there is an important place for reason and for natural morality derived from reason. Most significantly, the Catholic moral law tradition has long considered reason to be a reliable, though not perfect, guide to basic moral knowledge. According to this tradition, God imprinted natural law on reason so that basic moral truths can be known to rational people upon due reflection.

Though reason has been one of the major sources of Christian ethics, interest in the study of reason as the source or criterion of moral knowledge has waned significantly in the recent decades. This is in large part due to the wide influence of postmodernism in the field. Briefly, postmodernism is a school of thought that seeks to critique the notion of universal reason and the objectivity of knowledge. In particular, postmodern ethics has strongly assailed any appeal to universal morality and the rule of law based in reason.

Can reason, contrary to the claims of the postmodernists, furnish basic moral knowledge? In contemporary analytic moral philosophy, moderate intuitionism (distinguished from the classic intuitionism of Sidgwick and Moore) is gaining new momentum. Moderate intuitionists

(e.g., Audi and Shafer-Landau) claim that some basic moral truths are knowable through reason upon due reflection. They explain that this moral knowledge is supervenient upon natural facts without the former being reducible to the latter. Is Christian ethics compatible with intuitionism? If we consider reason to be an integral part of Christian morality and if we take revelation to be an additional resource to reason, it may be possible for Christian ethics to accept intuitionism. More importantly, Christian ethics can still draw upon other sources of Christian morality but also insist that reason plays a critical role in justifying Christian moral beliefs.

[Kierkegaardianism](#)

Perhaps the main representative for Christian existentialism is the Danish philosopher and theologian Søren Aaby Kierkegaard, (1813–1855) whose thinking had a broad but prominent influence on systematic theology, continental philosophy, literature, and arts. Within dogmatics, his thoughts have renewed and inspired both Christology (Karl Barth and Rudolf Bultmann) and Hamatology (Paul Tillich, Christof Gestrinch, and Wolfhart Pannenberg). Also, his view upon ethics and philosophy of religion has been innovative and of considerable importance in the process of rethinking Christianity on postmodern premises. Kierkegaard's status as founding father of existentialism is well known and recognized as is his concrete influence on Martin Heidegger, Gabriel Marcel, Jean Paul Sartre, and Albert Camus. Also, dialogical philosophy has been inspired by Kierkegaard's view on subjectivity and its relational nature, and Franz Rosenzweig, Martin Buber and Emmanuel Lévinas have through a critical dialog continued the inspirational path following from Kierkegaard's relational thoughts. Many authors, play writers, poets, and other artists from all over the world have also been inspired or bewitched by the Kierkegaardian universe.

At that time, Denmark changed from having been a feudal society into a capitalist society. Many people moved from the rural areas into the cities, which among other things caused that

the social structure changed from having been a rigidly hierarchical one to a relatively horizontal one. In its turn, this implied firstly that social identities were unusually fluid and secondly that there was a proliferation of normalizing institutions which produced pseudo-individuals. Hence, it became more and more difficult to find one's identity. One of Kierkegaard's greatest concerns was "how to become a Christian in Christendom." His concern about identity with a focus on Christian identity is why he is regarded not only as the father of existentialism but also as a Christian existentialist.

One of the major works done within Christian existentialism is *Begrebet Angest (The Concept of Anxiety)* (1844), in which he makes a revision of the traditional doctrine of original sin going back to St. Augustine. He emphasizes that sin always enters the world through the concrete sin of the single individual, whereby sin must not be understood as a hereditary deformity of human nature. In this work, he starts with analyzing the first anxiety experienced by human beings, namely, Adam's anxiety related to whether he should or should not eat from God's tree of knowledge. The act that he did eat from the tree of knowledge became known as the original sin. That he suffered from anxiety has also to do with Adam having a free will, the will to obey God (staying away from "that" tree) or not, to sin or not. According to Kierkegaard then, anxiety preceding sin is the presupposition for hereditary sin. However, anxiety also has the power to save individuals because it informs them of their choices, self-awareness, and personal responsibility. Anxiety is the bridge between unself-consciousness and self-consciousness.

In *Philosophiske Smuler eller En Smule Philosophie (Philosophical Fragments)* (1844), Kierkegaard writes under the pseudonym Johannes Climacus and sharpens the understanding of faith and Christianity. He takes his point of departure in Socrates, who presupposes that human beings posit the truth within themselves and therefore they can reach it in an immanent

way. As an alternative to this understanding, Climacus claims that Christianity presupposes that human beings are in sin by their own guilt and therefore it is not possible for them to relate to the truth by themselves but only through a transcendent power. From this thought stems the understanding of God as the absolute paradox.

Kierkegaard's doctrine of the absolute paradox is fully developed in *Afsluttende uvidenskabelig Efterskrift til de filosofiske Smuler* (*Concluding Unscientific Postscript*) (1846). In addition, this work is written under his pseudonym Climacus. The paradox is a key concept in Kierkegaard's attempt to interpret Christianity as a contradictory unity of time and eternity, which defies discursive understanding. The Christian paradox consists in the fact that the eternal truth is a paradox: the infinite God has become a finite human being at a certain point in history and as such has suffered death on the cross.

This is also shown in the doctrine of the stages as a theory about the relation between the three spheres of existence: the aesthetic, the ethical, and the religious. In the religious stage, the ethical commitment is combined with faith in a personal God (religiousness A), who not only demands obedience but also forgives human beings their disobedience, their sin, in Christ (religiousness B, or the paradoxical religiousness). The transition to religiousness B happens by a leap of faith.

In the authorship after 1846, Kierkegaard radicalizes his understanding of Christianity and stresses that suffering, martyrdom, and imitation are essential signs of true Christianity. *Kjerlighedens Gjerninger, Nogle christelige Overveielser i Talers Form* (*Works of Love, Some Christian Reflections in the Form of Discourses*) (1847) analyzes the relation between human love and neighbor love and represents Kierkegaard's contribution to Christian ethics. It is in *Works of Love* that the radicalization of Christianity and the critique of "Christendom," the notion of Christianity as a cultural artifact, are visible.

In *Sygdommen til Døden, En christelig psykologisk Udvikling till Opvækkelse*. (*The Sickness unto Death, A Christian psychological exposition for edification and awakening*) (1849) by anti-Climacus, the exposition of sin from *The Concept of Anxiety* is continued, and here Kierkegaard analyzes key concepts like despair and offence as constitutive for true Christianity.

Description

The rise of Christianity in Late Antiquity until its establishment as state religion of the Roman Empire led to a change in the societal status of various professions, including of physicians. Doctors lost their relatively independent position, since quotations from the Old and New Testaments indicated that God the Father and his son Jesus appeared as physicians and the medical art had to subordinate itself to Christian premises (Ex. 32.39; Lk. 5.31; Mk. 2.17).

From the sixth to the twelfth century, cloister medicine was the most important form of professional medical practice. It had already been codified in the “Institutiones” of the Benedictine monk Cassiodorus around 560, and in the following centuries, other monastic orders and the increase in the supply of resources (pharmacies, monastery gardens, collections of lore) expanded it. The Benedictines regarded medicine as part of lived faith. The initiative to establish and maintain medical facilities was the purview of the local heads of the Church; there were no defined medical curricula and qualifying tests. The medical knowledge of Antiquity was passed down in the Mediterranean region by Isidor de Sevilla and others, and in the following centuries, Irish and Scottish monks on missionary journeys spread this knowledge throughout the Occident, often in the form of copies or interpretations of the “Corpus Hippocraticum” and texts from Late Antiquity. Research done by Arab physicians also influenced Western Christian medicine.

The life work of Hildegard von Bingen is generally regarded as the high point of cloister medicine. Her nine-volume “Physica” comprises descriptions of the effects of about 500 medicinal plants, foodstuffs, elements, metals, and stones. It can be assumed that she had advisors assisting her in writing her books. Bingen describes how herbs are to be boiled up, smoked, and applied in powder form. Centuries of experience with monastic and folk medicine are summed up here and supplemented with therapeutic suggestions.

The cloister medicine of the High Middle Ages relied primarily on dietetics as a means of preventing illnesses or of rapidly restoring health by intervening to maintain the humoral pathological balance of humors, or body fluids. To this end, various poisons, phytotherapeutic medicines, or foodstuffs were employed; their power was supposed to be revealed solely to knowing and believing Christians and to be effective solely in the latter’s hands. Dosages varied greatly, depending on the region and the traditions of ancient writings. To recognize diseases and prepare the medication therapy, monks and nuns used the diagnostic method of uroscopy. Taking the pulse played only a subordinate role (in contrast to Arabic medicine). If the therapeutic measures taken did not seem to help, the medieval physician shifted to isolating the patient while continuing comprehensive pastoral care. In this way, it was possible to contain leprosy, for example.

In the course of the High Middle Ages, the proponents of cloister medicine lost their dominant position in the treatment of disease with the development of worldly educational institutions, the greater spread of physicians with private practices in the flourishing cities, and the development of folk-medicine networks. But, with their religiously argued concepts based on the ancient doctrine of the humors, all the healing professions had great difficulties treating the plague, or Black Death, after 1348. This failure of medicine led to intellectual unrest in occidental society.

In the following centuries, there was a gradual movement, repeatedly interrupted and influenced

by reverse tendencies, to break with the foundations of medieval healing arts. Anatomical investigations spread in the early modern period, the Reformation ended the dominance of cloister medicine for good, and the institution of state control instruments for the supervision of public health limited the Church's influence in the field of medicine.

Discoveries in physics, chemistry, anatomy, and geography increasingly made it difficult to explain disease in terms of divine influence. There was a final unfolding of Christian healing cultures in the period of idealism, in which the invocation of the healing vital powers harmonized with the idea of a comprehensive system of dietetics and an appeal to humoral pathological approaches that integrated the discoveries of the natural sciences since 1750. The discovery of the law of the preservation of energy, the development of inorganic chemistry, cell pathology, and bacteriology, as well as the spread of Charles Darwin's theories lastingly destroyed Christian healing cultures' theoretical foundations and attempts to explain the behavior of the human organism. In the decades after 1880, Christian physicians reoriented themselves toward issues of medical ethics. They thereby adhere to static, unchanging moral principles, for example, placing the right and duty to live above all secular considerations. They can, but need not, have a rejecting attitude toward Darwin's theory of evolution. This is true also of the clergy who appeared as forerunners of modern complementary medicine, for example, the hydrotherapist Sebastian Kneipp and the "clay pastor" Emanuel Felke, who combined naturopathy and homeopathy. Homeopathy itself entails belief in divine curing power and can thus be regarded as located on the margins of Christian healing cultures.

Self-identification

Science

The adherents of Christian healing cultures were for centuries the sole practitioners of natural scientific, medical, and transcendental research in

Europe. The question of scientific validity did not arise in this period. After the loss of this position in the nineteenth century, explicitly, Christian doctors have regarded themselves as belonging to conventional medical culture but claim to be the sole representatives of special ethical principles.

Religion

The basis for these actors' work is the Christian religion. They regard themselves as agents of the divine will.

Characteristics

While clergy are primarily concerned with the welfare of people's souls in the afterlife or beyond, representatives of the healing cultures are mainly engaged for health in this world. They thus function both as a marginal organization and as a special complex within an increasingly secularized Christian world.

Relevance to Science and Religion

The representatives of the healing cultures regard themselves as an integral component of the Christian world, and they are recognized as such not only by their hierarchical superiors but also by some vehement opponents of Christianity. In missionary regions, they are especially often the targets of terrorist attacks.

Sources of Authority

They derive their authority from two sources: first, their success in treating patients and second, their membership in the clergy of the Churches.

Ethical Principles/Key Values

The fundamental principle of Christian healing cultures is the orientation toward a Christian

worldview. This means that one sees oneself as the agent of the divine will and that the only ethical guidance one accepts is the Bible, divine revelation, and the doctrines of salient Church scholars (for example, popes).

Conceptualization

The same conditions for action, regulations, and considerations are valid as for all actors of the Christian Churches. The attitude toward death has a special role: adherents of Christian healing cultures stand in a dilemma in this regard. On the one hand, they see it as their duty to preserve life; on the other hand, reverence for the divine indirectly obligates them not to interfere in its workings. Here, individual case decisions dominate, for example, in questions of life-extending measures, abortion, and whether to regard brain death as the end of life. Standards on these questions are not unified in either Protestant or Catholic communities of faith.

Christian Theology

► Constructive Theology

Christianity

Lluís Oviedo

Pontifical University Antonianum, Roma, Italy

Description

Christianity is, from a historic point of view, a religion born from the life, preaching, and destiny of Jesus, called “the Christ” by His followers. The collected memories about that man gave rise to a growing network of communities in the first century A.D., forming what has been designed ever as since “the Church.” This institution has fixed doctrines, codes, and ritual practices that constitute a tradition going back over 20 centuries, and diversifying into many expressions or “denominations.”

Scholars have pointed to a broader sense of “Christianity” beyond the institutional boundaries of the churches and their creeds and even beyond the limits of organized religion. It reflects rather an “idea” or understanding of reality, based on concepts such as “► [incarnation](#)” – the continuity between the divine, human, and immanent reality; “redemption” – the assumption that evil can be overcome through repentance, sacrifice, regeneration, and radical love. This is a rather cultural program that influences our way of seeing human nature, society, and the whole of reality. Obviously, this second sense of the word presupposes a tradition too, even if it feels less bound to doctrinal constraints or to institutional duties.

Concerning developments, it is worthy to take into account the following: denominationalization, modernization, secularization, and revival.

“Denominationalization” refers to the steady fragmentation of Christian churches into ever smaller communities, trying to adapt to social, cultural, and ethnic niches, resulting in an extensive pluralism of expressions. As a result of this fragmentation process, seen primarily in the Americas, the “internal competition” between denominations has increased, dynamizing most

of the churches in many areas. This competition contrasts with religious entities living in a regime of monopoly, such as the state religions of Europe. However, the fragmentation process has at the same time brought confusion resulting in too many contrasts, endangering any ecumenical attempt or sense of communal belonging.

“Modernization” can be considered together with “rationalization” as forms of adaptation to modern times and societies. Christianity – in its many expressions – has attempted to renew itself assuming formats that try to be more fitting in advanced societies. This process has been pioneered by the so-called ► **“liberal” theology** and churches but is characteristic of many denominations struggling to survive in cultural environments radically different from those that existed in their historical beginning and long tradition. Many strategies have been tried. Not every attempt has shown equal effectiveness.

► **Secularization**” is closely linked with modernization since it refers to both: the process of assimilation of Christian communities to their modern, secular entourage, discharging part of their own “religious burden;” and the negative effect of an increasingly secular society that erodes the influence of churches and lowers the levels of commitment of their faithful. This development is threatening the continuity of many Christian entities in Western countries; it is indeed the religious tradition most affected by such a disruptive tendency. This circumstance has caused many scholars to think that Christianity is intrinsically a “secularizing” religion or is worldly driven by its own structure and identity.

“Revival” goes against the former tendency. It describes movements that, in a cyclical way, have since the ninetieth century brought constant impulses of enthusiastic missionary engagement, revitalizing entire churches or big sectors of them. Over the last few decades, there have been several waves of revival, most at the hands of Evangelicals and Pentecostals, bringing a deep transformation of Christianity in many regions of the world, beyond the local traditions that have been present for many centuries.

Characteristics

Reflecting about the most distinctive traits of Christianity, the following can be proposed: the idea of ► **incarnation**, of redemption, of community, and of the human. The “incarnated God” is perhaps one of the most exclusive doctrines among developed religions; even if it finds roots and similarities in many other religious traditions, the most far reaching has been this faith: stating that God becomes man, and hence the divine becomes worldly, breaking the usual separation between transcendence and immanence. The idea of a “suffering God” to redeem or liberate humankind is also unique. Christianity proclaims that God incarnated suffers an atrocious death to rescue humans from ► **evil** and ► **death**. Even if this is an archetype of the religious mind, Christian faith has brought this motive to its latest consequences. The idea of community or church is intrinsic and distinctive to Christian faith and praxis, which encourages the formation of social units, presided over by the law of mutual ► **love**, forgiveness, and engagement. The Christian ► **anthropology** assumes a particular format, describing human beings as “images of God” fallen into sin and self-destructive tendencies but rescued by grace to live a new life in faith and love. Such a distinctive anthropology is the base of Christian view of human dignity, rights, and respect.

Christianity is clearly distinctive among other religious traditions. This distinction probably works in a clearer way with some of them and less with others. Christianity, for an instance, is very close to ► **Judaism**; indeed, it shares a good deal of its sacred texts and values; some of its ritual practices have been inspired by Jewish ► **rituals**, and the boundaries between both religions sometimes become fuzzy. The distinction is clearly sharper regarding Eastern religions, like Hinduism and ► **Buddhism**; there is often a completely different worldview, anthropology, and values system. Often in recent times, the distance has prompted greater interest in these Eastern religions, while at the same time the proximity has sometimes nourished misunderstanding and hostility.

Relevance to Science and Religion

Christianity is one of the religious traditions more involved in the area of “science and religion.” Just looking at the data of specialized societies membership, scholarly papers, and books, there is an overwhelming majority of Christians among the practitioners of that subdiscipline. However, some nuances seem pertinent at this point. Not all Christian churches are involved in a similar way in that endeavor, indeed rather a minority of them. And only some of their theologians have shown interest on this field. Some historical developments need to be recalled. Christian thought was very committed to contemporary expressions of reason and science during middle ages. At some point in the ulterior history, a deepening differentiation began to grow between the realms of theology and sciences. Even if many scientific developments up until modern times were delivered by clergymen and very committed Christians, the growing tendency has been a rising independence between both realms, and even a mutual ignorance and discredit. Some Christian branches have been more interested in scientific progress, especially the liberal ones, while those more orthodox or traditional usually found themselves suspicious about the scientific milieu and progress.

The current situation is heir of the split experienced during the last century and reflecting two different mentalities: one more engaging with their own culture, society, and time; and other marking more its distinction, sometimes reacting to contemporary developments, and proclaiming the self-sufficiency of faith before the perceived threat of competing ideas or world-views. At the present, some churches stress more than others the importance of engaging in a serious dialogue between faith and reason that obviously includes the sciences. It happens that most revivalist Christian expressions often – if not always – refuse to go into a mutually engaging relationship with science.

It is not easy to assess the implications that “science and religion” as a living steady dialogue have in the real life of Christian churches. Probably the reach of this effort is rather short and its

influence small, even at the level of teaching or formation of leaders. The expectation is that a greater awareness of the risks born from ignoring the challenge. The opportunities involved in this dialogue may prompt a deeper engagement from theologians and pastors to an adequate Christian message to a cultural environment massively influenced by science.

Sources of Authority

The most important source of authority for all Christian churches is the Bible, which is nevertheless interpreted in various ways, in a spectrum that goes from more fundamentalist to more flexible forms of understanding the sacred text; these distinctive positions correspond with the identities and styles of different Christian denominations. Indeed for those more “Evangelicals,” the Bible becomes the only authority to be taken into account. What makes the Bible authoritative is its character of being “revealed” by God, in the sense of transmitting God’s will and message for humanity; no other text shares this unique characteristic.

Other Christian churches stress the value of traditions codified in dogmas or corpus of doctrines and the authority of the so-called Big Tradition, including the most recognized masters of the ancient and medieval church; this is more present in some traditional churches, like Catholic, Eastern Orthodox, and, to some extent, the Anglican Communion. Other sources of authority depend on the structure and organization of the churches. Every church has its distinctive authorities, like the Pope and councils for Catholics, the bishops for many traditional churches, or pastors in others. Theologians usually keep some authority but almost always only in the academic field. Indeed, there is a clear correlation between type of authority – more or less centralized – and the unity or cohesion of a church.

The question of authority is today closely linked to choices about the most effective way to preserve a church’s own identity and to adapt to changing times. Decisions need to be made after the perceived need to cope with different aims: to keep unity – and to be able to diversify – to be

faithful to tradition, and to be open to dialogue with contemporary reason. From the tensions between the extremes and the search for balance, different strategies and ecclesial forms arise.

Ethical Principles

The main ethical principle for Christians is the commandment of ► [love](#). This is however a too broad stance to become meaningful. Indeed, the Christian idea of love has gone through many discussions and knows a certain degree of pluralism. Some consensus has been reached resorting to philological analysis: love expresses at least three different attitudes: renouncement of self for the benefit of others (► [agape](#)), emotional attraction and engagement (*eros*), and friendship that implies mutuality (*philia*). Christian love represents some pluralism of expressions, or would try to keep some balance between these three dimensions, even if the first one has seemed for an entire modern tradition the most pertinent or specific to Christian identity. In any case, love is proposed in radical terms in the canonical Christian texts and experiences: as a disposition to sacrifice one's own life for God and for others or as complete forgiveness and love even to one's enemies.

Key Values

The key values of this tradition are in tune with the described ethical principles. However, broadening the presentation, it could be stated that the key values are those of ► [faith](#), ► [hope](#), and ► [love](#). Briefly, faith refers to an attitude of complete trust in God that invites one to follow His will as expressed in His revealed texts; this is a more of a behavioral than a cognitive disposition since faith not only assumes a code of beliefs but also a way of living. Hope is born from faith and expresses a conviction that God will accomplish His promises and will deliver His blessing and will provide a good life to everybody who follows the Gospel. Hope is lived even if apparently those without faith or far from divine commandments are better off, while many believers

need to struggle. The value of love has been already exposed. Probably other values rank high in this tradition as well, like the disposition to ► [conversion](#) or changing one's mind and life in the pursuit of ► [truth](#) and salvation. However, trying to become more concrete and essential, the highest value for Christians would be to feel God's presence and love, which explains the interest and passion of mystics, a special branch of very committed Christians, as a way to better express this superior value.

Relevant Themes

There are several questions that clearly interfere in the relationship between Christian faith and science and that need to be taken into account:

- *Cosmological issues*, especially concerning the origin of the universe, are important because creationists are indeed a branch of Christian fundamentalists, and they are clashing vehemently with evolutionists and scientific views in general, endangering a peaceful dialogue with science. There is nevertheless a mainstream of Christians who take for granted a compatibility of the Christian doctrine describing God as creator and provident, and the scientific view of reality. There is furthermore a sometimes diverging way to understand time, the possibility of God's action, and the limits of the real, including the limits of science. These are points of contention but not of exclusion preventing a fruitful interaction.
- *Anthropological issues* are important because few religious traditions are committed to a view of human beings exalting their dignity, freedom, and spiritual dimension, as Christianity does. Such a view has been rendered less plausible after the rise of more scientific anthropologies. This poses problems of mutual understanding and criticism since it tries to debunk some of the Christian traditional insights. Secular humanists have often led the censure against reductive views of human beings born by scientific developments; Christians are probably more akin to this humanist position.

- *Social issues* are important because the Christian view of society is tailored after ideals of “God’s Kingdom” expressing a growing fraternity, while the models derived from social sciences – especially economics and political science – often conflict with the expected Christian idea of human organizations and social links, giving rise to divergent paths of social progress.

Mainstream Christianity aims at offering a positive contribution for the progress of humankind; however, sometimes its way to understand what is better for humans contrasts with what other voices deem as better. In the end, a dialogue is necessary that can be built on different models and values, not just on issues of detail.

Introduction

Fundamental physics deals with some of the most general, abstract, and basic concepts in our view of the world such as space, time, mass, energy, interaction, or causality. The revolutionary changes in fundamental physics have challenged our usual concepts and view of the world leading to a prompt philosophical rethinking of some of our basic presuppositions in the description of nature or even a fundamental reorientation with regard to our cognitive or ontological positions in relation to the world. The emergence of quantum theory is a paradigmatic example of such revolutionary change.

The elementary, nonrelativistic *quantum mechanics* is without any doubt the most widely discussed and controversial theory in modern physics. It is routinely considered to be the empirically most successful theory of twentieth century physics and, at the same time, to be incomprehensible, mystifying, or intrinsically anti-realistic. Its relativistic generalizations in the form of *quantum field theories* provide the conceptual framework which is at the basis of the so-called *standard model* in modern particle physics, that is, the fundamental theory of elementary particles and basic forces in the universe. However, quantum field theory inherits all of the strangeness of quantum mechanics and adds some of its own. This is why most of the discussions have been focused on elementary quantum mechanics. Here the problems may be seen clearer and, furthermore, it is often thought that we have to get a proper understanding of elementary quantum mechanics first, before we can hope to disentangle the open issues in quantum field theory (Cushing 1988).

Two of the main issues of quantum mechanics are the questions about *realism* and *intelligibility*, that is, (a) Can the theory be seen as an objective description of an independent physical reality? and (b) Is the theory physically understandable, that is, does it provide us with an understanding of the physical world? Certainly these issues are connected in the sense that, in so far as we are realists about the physical world and want our theories to give a realistic account of the world,

we also tend to demand that this account is understandable. Conversely, we often say that if a theory is not understandable it cannot be accepted as a realistic description of reality. The alternative would be to admit that the human mind cannot understand reality – which most physicists and philosophers would regard as an admission of a defeat in the scientific enterprise.

Now, these broad concepts of *realism* and *intelligibility* are actually full of pitfalls, as we shall see later. For now we may just record the fact that the main concerns about quantum mechanics are that it is (a) *not realistic* and/or (b) *not intelligible* or, in brief, that it does not provide a *realistic understanding* of the quantum-world.

Intelligibility and Realism

There is no doubt that quantum mechanics is non-intuitive in so far as it is both (a) non-picturable (non-visualizable) and (b) radically contra-intuitive or “strange” in the broader sense of being very different from everything we are accustomed to – both ordinary common sense experience and classical physics. The difficulty, however, is in deciding what exactly to make out of this. First, it is difficult to give an absolute sense to the notion of strangeness or contra-intuitiveness (b), for things are either strange or not strange relative to our expectations – formed from earlier experience – or theories, and if we systematically rejected everything which seemed counterintuitive in the light of established knowledge, then we would never discover anything really new (non-Euclidean geometries, theories of relativity, the heliocentric world-picture, Darwinian evolution, etc.). Intuitiveness in the narrower sense of picturability (a) appears to be more absolute – at least if it is released from the vague notions of mental imagery and defined in terms of the possibility of a comprehensive model in space and time – but it is still unclear if this is really necessary for intelligibility: Aren’t there a lot of things which we may claim to understand but which are not picturable in this sense?

And, even so, it is not at all clear why reality should conform to this standard. Our ordinary experience unfolds continuously in space and time and so does the world according to classical physics, but it would be a sheer prejudice or anthropomorphism to suppose that the micro-world has to conform to such conceptual structure. Therefore, we should be aware of uncritically identifying or even defining intelligibility in terms of criteria borrowed from ordinary experience or classical physics. And furthermore, we should be even more careful of using such established or accustomed notions of intelligibility as criteria for realism.

As for realism, it is important to recognize that *realism* is a transitive concept. You cannot just be a realist full stop, that is, a realist about nothing in particular. The realistic stance is always *about* something X (which may be God, platonic ideas, the physical world, moral values, or whatever) where X is the *ontological content* of the realism in question. In this sense, the formal scheme for realism is (1) X exists objectively, that is, independently of our minds and knowledge (*metaphysical realism*) and (2) we have or may obtain knowledge of X (*epistemological realism*).

Actually, standard accounts of the so-called *scientific realism* are variations on this scheme: We are scientific realists in so far as we (1) take scientific theories as true or false accounts of the objective world (metaphysical component) and (2) take sufficiently well-confirmed, explanatory, successful, etc., scientific theories as true (approximately true, valid in a given domain or the like) theories of the objective world (epistemological component) (Ladyman 2007, p. 335f; Chakravartty 2007, Chap 1). Such definitions are, as they should be, quite neutral with regard to *which* theories actually are true or should be accepted as true, that is, they are quite neutral with regard to *what* actually the world is like and *what* kind of entities and structures our best theories are going to introduce in our scientific world-picture.

Nonetheless, in the quantum-discussions the concept of realism is handled with much less care in so far as questions of realism are often mixed

up with questions of ontology. When it is said that quantum mechanics is intrinsically anti-realistic just because it does not exemplify universal value-definiteness like classical physics, quantum mechanics is actually measured by the standards of classical physics, by criteria of reality borrowed from the ontological framework of classical physics. In this sense, it is actually just a complaint that quantum mechanics is not like classical physics. Gibbins refers to this highly widespread attitude when he says: “Realism in the philosophy of quantum mechanics means the idea that quantum systems are really like classical particles” (Gibbins 1987, p. ix).

In exactly the same way, the arguments that quantum mechanics is necessarily anti-realistic *just because* it is intrinsically probabilistic, or *just because* it contains discontinuities in the time-development (measurement collapse), or *just because* it does not give us a spatiotemporal picture of the quantum world are implicitly using criteria of reality which stem from classical physical experience and which are at home only in the classical physical world-picture or ontology. The same, of course, goes for the general attitude that quantum mechanics must be false or meaningless as it is “strange” or “weird” in the broader sense that it is contra-intuitive in terms of our ordinary experience or classical physics.

We should clearly separate *questions about realism* from *questions about ontology*, that is, questions about the particular nature and structure of physical reality. Every fundamental physical theory contains a physical ontology and very different physical theories may contain very different physical ontologies, which may involve different conceptions of intelligibility and even different criteria of what counts as a realistic description. We are not just physical realists or not (at least unless one is simply denying the very existence of the physical world), but realists concerning some particular physical theory(ies) or other and therefore *about* what this theory(ies) says(say) about the world, and hence *about* some particular physical ontology. As all known physical theories are ascribing *states* to *physical systems*, lay down dynamical *laws* for the time-evolution of the states, establish

connections between states and *observables* (alias *physical quantities*), and eventually introduce *fundamental physical constants*, we may say that full-fledged realism concerning physical theory T involves something as follows:

- (R) (a) Realism about the kind of *physical systems* described by T (i.e., *entity-realism*)
- (b) Realism about the *state-descriptions* and *dynamical laws* of T (i.e., *physical state-realism* and *nomic realism*)
- (c) Realism about *observables* which are well defined on the state of the physical system concerned, including the *values*, if any, of such observables (*realism about observables* or *quantities*)
- (d) Realism about any *fundamental constants* figuring in T (*universal constant realism*)

In this sense, physical realism may be said to be realism concerning a particular physical ontology, namely, the ontological structure obtained by concretely completing items (a–d) for a particular physical theory or set of theories. In terms of such a scheme one may be a realist about different physical theories and so about quite different physical ontologies. No particular physical theory or associated physical ontology can be said to *define* what physical realism is.

Classical Realism

Classical physics is fundamentally classical mechanics and classical field theory which, of course, are quite different theories associated with different physical ontologies, namely, a classical particle ontology and a classical field ontology. If classical particles or classical electromagnetic fields are put under items (a), (b), etc., in the scheme (R), realisms will be obtained for the different ontologies of classical particle mechanics and classical electromagnetism (Hebor 2005, p. 39). Nonetheless, and this being the important point here, there is an underlying ontological deep structure common to all of

classical physics of which classical particle and field theories are just variants, and which sets classical physics apart from quantum physics – and so actually justifies the contrast *classical* versus *quantum* physics. This ontological structure is such a deep-seated, well-integrated conceptual framework, involving its own criteria of objectivity, completeness, intelligibility, and reality, that the acceptance of this conceptual framework may be defined as a particular kind of realism, namely, a *realism concerning classical ontology* or, briefly, *classical realism*. As this ontology is presumably more familiar to most people than is quantum ontology, this entry has been presented very briefly (for details cf. (Hebor 2005, Chap. 3)). It could be formally described by means of the following:

Basic Classical Ontological Structure

- (1) *Classical state-observable structure*:
 - (a) Every state S of a classical physical system is a real function of (in principle) observable physical quantities (called *state variables* or *observables*) o_s and is represented by real numbers: $S(o_{s_1}, \dots, o_{s_n})$;
 - (b) The state $S(o_{s_1}, \dots, o_{s_n})$ uniquely determines the value of every other observable $o_{\bar{s}} \notin \{o_s\}$ pertaining to the system in state S , so actually (the values of) all observables o pertaining to a system are functions of the small set of state observables $o(o_s)$.
- (2) *Value-definiteness*: Every observable in classical physics has (at all times) a definite value, namely a real number, for every physical system for which it is defined at all.
- (3) *Space-time character of observables*: Classical observables are defined in space-time, that is, every observable o_k is a function that essentially includes space and time in its domain of definition: $o_k = f(a, b, \dots, \mathbf{r}, t)$, where $a, b, \dots$ may be other physical quantities, themselves being observables, $\mathbf{r}$ a position vector, and t time.
- (4) *Non-quantum postulate* (continuity): The state observables o_s and hence the states are continuous functions of time, and classical physics allows continuity of fundamental

physical interactions, that is, there is no limit to the gradually turning off an interaction: for any positive ε the physical action ($\text{Energy} \times \text{Time}$ or $\text{Momentum} \times \text{Length}$) may be less than ε .

Comment: This excludes any Planck-like constant like $\hbar$.

(5) *Classical non-superposition of states:* (a) At any time t a classical system is in a definite state (by (1) and (2)); (b) no state S is a superposition of states S_1 and S_2 such that any observable o_S belonging to S is not simply a function $o_S = f(o_{S_1}, o_{S_2})$ of observables belonging to S_1 and S_2 and hence value-definite.

(6) *Separability:* Any classical state for a composite system is *separable*, that is, it may at any time t be thought of as composed of independently existing, spatially coordinated, physically well-defined sub-states pertaining to (a) the constituent subsystems and hence (by (3)) to (b) every spatial domain or location of the composite system in question.

Comment: Note that this does not mention interactions between physical (sub)systems and so is *not* a locality principle. Principles of *general locality* (no actions-at-a-distance) or *relativistic locality* (no super-luminal interactions) hold in both classical and quantum physics. However, separability means that any correlations between observables pertaining to distant systems have to be by way of present causal interactions or common causes.

(7) *Classical determinism:* The specification of state at any time t_0 uniquely determines (by way of dynamical laws which may be represented as differential equations: Hamilton's equations, Maxwell's equations, etc.) the state of the system at any other time t (for an isolated system). Any lack of knowledge of future states (predictability) is purely epistemic, not ontological, and this also goes for the so-called *chaotic systems*.

Comment: By (1) this means that *all* observables for the system at t are determined by the state at t_0 .

Consequences for Classical Physical Epistemology

(8) *Classical description:* Observed and unobserved systems are described in exactly the same way. That is (a) observed systems are (ideally) described as if they were unobserved and (b) unobserved systems are described as if continually observed. In brief: observation or measurement does not figure at all as an essential (non-eliminable) factor in theoretical description. This means more particularly

(a) *No measurement problem:* Any measurement-interaction is continuous and may be neglected or controlled so that the observed system may be described as if the measurement-interaction actually was nil (*Ideal of detached observer*).

(b) *Visualizability:* Unobserved systems are described as if they were subjected to optimal, idealized observation (a *God's eye-view of the world*).

Comment: (8b) should not be understood in the sense of mental imagery (mental images of four-dimensional curved space-time or even $d\mathbf{r}/dt$ cannot be formed in classical physics) but rather in the sense of a comprehensive, continuous geometrical picture in space and time. In this sense (a) classical *states* are visualizable in as much as systems and observables are embedded in a comprehensive spatial model and (b) classical *processes* are visualizable in the sense that any time-evolution is seen as a continuous sequence of states in time.

Comment: In this regard, classical physics is in fact much more tied to observational categories than is quantum mechanics. As classical states are functions of value-definite observables the world is actually described as if continuously observed by an omnipresent, detached observer.

(9) *Classical completeness:* A complete description of the state of a physical system must by way of the state-observables (implicitly) specify the values of all observables pertaining to the system.

Comment: Any lack of value-definiteness in the description is, thus, a sure sign of the incompleteness of the description.

- (10) *Classical objectivity*: A physical description D of a physical system S is *objective* in so far as D represents S as it is in itself, that is, the nature and state of S as it *is* or *would be* independent of the description D , including any experiments or measurements that may underlie D .
- (11) *Classical realism*: Physical systems (a) exist objectively, that is, independently of any (physical) description and of any consciousness, and (b) they always exist objectively in definite *classical states* and hence also (c) are objectively characterized by *definite values for every observable* pertaining to the system. Furthermore, (d) *universal constants*, if any (like c in relativity), are integral parts of the state-description and so have objective existence.

Comment: These are just (a–d) in the general scheme (R). It should be clear that the traits specific to classical physics are contained in items (b) and (c), that is, the classical structure for states and observables, namely, (1) and (2) above.

This classical realism (11) with its associated ontology (1–6) and epistemology (7–10) is largely a quantitative refinement and extension of our ordinary empirical common sense with regard to our macroscopic environment. Hence, this kind of conceptual structure seems to be deeply ingrained in our instinctive way of seeing the physical world. Quantum mechanics, however, presents quite another conceptual structure if seen as a realist description of physical reality.

Quantum Realism

Quantum realism could be formally described by means of the following:

Basic Quantum Ontological Structure

- (1) *Nonclassical state-observable structure*: (a) Every (pure) state of an *individual* quantum system is *completely* represented by a normalized vector (*state vector*) $|\psi\rangle$ in a complex, linear vector space with inner

product H (*state space*, *Hilbert space*). (b) Observables (dynamical physical quantities) $A, B, \dots$ are represented by generally non-commuting linear self-adjoint *operators* $\hat{A}, \hat{B}, \dots$ acting on vectors in H , each defining a spectrum of definite *eigenvalues* $\{a_1, a_2, \dots\}$, $\{b_1, b_2, \dots\}$ and an associated set of *eigenvectors* $\{|\alpha_i\rangle\}$, $\{|\beta_i\rangle\} \dots$ satisfying *eigenvalue equations* $\hat{A}|\alpha_i\rangle = a_i|\alpha_i\rangle$, $\hat{B}|\beta_i\rangle = b_i|\beta_i\rangle \dots$, such that each set of *eigenvectors* $\{|\alpha_i\rangle\}$, $\{|\beta_i\rangle\} \dots$ provides complete, though (generally) different, *eigenbases* for the state space, that is, every state vector in H may be expressed as linear combinations of state vectors for the various operators $|\psi\rangle = \sum_n \langle\alpha_n | \psi\rangle |\alpha_n\rangle = \sum_n \langle\beta_n | \psi\rangle |\beta_n\rangle = \dots$ = the same state vector in different *representations*.

Comment: For convenience (1) considers only the discrete case. For operators with continuous eigenvalue spectra the sums must be replaced by integrals. The fact that $|\psi\rangle$ represents *individual* systems is what separates quantum realism from *statistical ensemble interpretations*, and that it does so *completely* is what separates it from *hidden variables theories* (see below). It should further be noticed that neither the abstract state vectors nor the operators by themselves provide any physical information. The state-observable structure of quantum mechanics is an *integrated vector-operator structure*.

- (2) *Value-indefiniteness*: In a quantum state $|\psi\rangle$, there are generally no definite values for any of the physical observables, the exception being when $|\psi\rangle$ is an *eigenstate* for observable A (eigenvector for $\hat{A}$). Furthermore there are never definite values for all observables pertaining to the systems in question, there being no common eigenbases for non-commuting operators, $\hat{A}\hat{B} \div \hat{B}\hat{A} = i\hat{C}$, so that $|\psi\rangle$ being an eigenstate for $\hat{A}$ entails $|\psi\rangle$ generally *not* being an eigenstate for $\hat{B}$ but rather a superposition of such states $|\psi\rangle = \sum \langle\beta_n | \psi\rangle |\beta_n\rangle$, and vice versa. For canonically conjugate observables like position and momentum there are no common eigenstates at all, the commutator being $\hat{Q}\hat{P} \div \hat{P}\hat{Q} = i\hbar$ and resulting in the famous

Heisenberg relations $\Delta q_i \Delta p_i \geq \hbar/2$. What the vector-operator structure *does* allow, however, are *definite values* when $|\psi\rangle$ is an eigenstate of $\hat{A}$, $\hat{A}|\alpha_i\rangle = a_i|\alpha_i\rangle$, specification of the *possible values* for observable A (spectrum of eigenvalues for $\hat{A}$), *probabilities* for getting result a_i in a measurement of A on a system in state $|\psi\rangle$, $P(a_i||\psi\rangle) = |\langle\alpha_i|\psi\rangle|^2$ (*Born-rule*) and *expectation values* $\langle A \rangle = \langle\psi|\hat{A}|\psi\rangle$.

Comment: The universality of definite values in classical physics is, thus, replaced by largely probabilistic magnitudes. It is, however, crucial that the theory does provide non-probabilistic information by way of eigenvalue spectra and actual eigenvalues too. Any statistical test of expectation values and transition probabilities has to be done in terms of actual and not just possible values for observables. Hence, the importance of the measurement collapse into eigenstates for the measured observable.

(3) *Non-space-time character of observables:*

Corresponding to the general value-indefiniteness, quantum operators are defined on state-space and not physical space-time.

(4) *Quantum postulate (discontinuity):* Quantum mechanics is based on the fundamental constant $\hbar$ with the dimension of *action* ($\text{Energy} \times \text{Time} = \text{Momentum} \times \text{Length}$). The finite value of $\hbar$ entails a fundamental discontinuity in all quantum interactions (even though eventually hidden by the superposition principle as in *quantum entanglement*, see below).

Comment: The discontinuity does not show up in the continuous time-development of the Schrödinger equation for an isolated system, but reveals itself with a vengeance in the measurement collapse.

(5) *Quantum superposition of states:* It follows from the very vector structure of quantum mechanics that a (normalized) linear combination of two different states is a new state (*superposition principle*), and it follows from the completeness of eigenbases that any state may be expanded as a linear combination of any operator from the same state space.

Thus, $|\psi\rangle = \sum_n \langle q_n | \psi \rangle |q_n\rangle = \sum_n \langle p_n | \psi \rangle |p_n\rangle = \dots$, which means that $|\psi\rangle$ at the same time may be in a superposition of position eigenstates $|q_i\rangle$ and momentum eigenstates $|p_i\rangle$ with neither position nor momentum definite.

Comment: The superposition principle in itself entails value-indefiniteness, and in contrast to some interpretations of the Heisenberg-relations, it is clear that this kind of value-indefiniteness is not a result of measurement-disturbances. The value-indefiniteness here is ontological – the system simply *has not* definite values for position and momentum – if you accept the reality of quantum states. Such superpositions cannot be described in classical language and it is important to be aware of attempts to do so in popular and semi-popular expositions.

(6) *Non-separability or entanglement:* Quantum states for composite systems which have interacted in the past generally are not separable, that is (for a two-particle system), the state for the composite system $|\Psi\rangle_{12}$ cannot be expressed as a product of single-particle states, $|\psi_i\rangle_1 |\psi_j\rangle_2$, but instead has to be expressed as a sum (integral) over such product-states: $|\Psi\rangle_{12} = \sum a_{ij} |\psi_i\rangle_1 |\psi_j\rangle_2$. In such *entangled* or *non-separable* states (a) there is a well-defined quantum state for the whole system but individual states for the component systems are not defined at all, which (b) shows itself in the fact that there are correlations between the results of the possible measurements on the two particles – correlations which are quite independent of the distance.

Comment: It is worth noticing that non-separability is just a consequence of the superposition principle for many-particle systems in that the entangled states are simply superpositions of different product-states for the component systems involved. The existence of non-separable two-particle states lay at the root of the original version of the *EPR-paradox* (Einstein et al. 1935) and has, in general, been a subject of extensive discussions on the foundations and interpretation of quantum mechanics. The simple example

of the spin- $\frac{1}{2}$ singlet state $|\Psi\rangle_{12} = 2^{-\frac{1}{2}} [|+\rangle_1 |-\rangle_2 + |-\rangle_1 |+\rangle_2]$ shows the essential features. Regardless of the distance between the two particles and regardless of the spin direction chosen to measure, opposite values are always to be obtained (perfect anti-correlation) as long as the measurement is done along the same direction on both particles. And if different measurement-directions are chosen for the two particles, stronger correlations may be obtained than that is possible if the particles were in separable states, which is the content of *Bell's inequality* (Bell 1964; Auletta 2000, Chap. 34f.). The existence of such strong quantum-correlations has since been amply confirmed experimentally, but this result unfortunately is often summed up in the statement that *local realistic* theories are ruled out – that is, if realism is maintained the correlations can be accounted for only by introducing non-local (superluminal) interactions between the particles – and that quantum mechanics is nonrealistic. Actually Bell's theorem follows from the twin assumptions of *separability* and *locality* so what is called “realism” here is not *realism* but the *separability* assumption in classical physics (Hebor 2005, Chap. 5). This is a clear instance of the fallacy of confusing *physical realism* with the specific assumptions in *classical ontology*, that is, with *classical realism*. Further, *non-separability* should not be confused with *non-locality*, for in as much as the component systems have no individual states it has no sense to speak of interactions between the systems. Beyond this it can be proved that non-separability cannot be used for any kind of superluminal communication (Auletta 2000, p. 633f.).

(7) *Quantum determinism and indeterminism:*

The time-development of state vectors for isolated systems, the so-called *unitary time-evolution* as given by the *time-dependent Schrödinger equation*, $\hat{H}|\psi\rangle = \div i\hbar \frac{\partial |\psi\rangle}{\partial t}$, is as deterministic as any classical dynamical law (being given by a first-order differential equation). The state vector, however, generally does not contain values for the observables (and never for all, cf. (2)), and obtaining these by measurement introduces the

indeterministic feature in so far as for non-eigenstates the theory only gives probabilities for different results within the spectrum of possible results (the Born-rule).

Comment: Whether this is of any relevance for human freedom is at best unclear. It is not clear that the human brain operates by measurement-like collapses on quantum-level, and beyond that it is not clear that human freedom can be identified with pure chance.

Consequences for Quantum Physical Epistemology

(8) *Quantum description:* Unobserved systems are represented by abstract state vectors, and state vectors are not observables. Observed systems are described by the result of operators acting on state vectors. Definite values for observables are generally obtained at the cost of non-eliminable interactions with the system, resulting in discontinuous collapse of the state vector. This leads more particularly to the following:

(a) *Measurement problem:* The question of what is necessary and sufficient for collapse, and where the boundary between quantum superpositions and the definiteness of macroscopic bodies is, is an unsolved problem (Auletta, pt. IV). It is sometimes inferred from this that we should deny the existence of state-collapse and try to apply the superposition principle even to macroscopic bodies (*Non-collapse theories*, see below). Another response, however, is to say that the domain of the superposition principle is what is at present not known and thus, something to be investigated rather than just replacing the lack of knowledge by extrapolations (Primas 1983; Hebor 2005, Chap. 6).

(b) *Non-visualizability:* The description of unobserved systems by state vectors means that the quantum world is radically non-visualizable. From a quantum realist point of view, however, $|\psi\rangle$ has to be regarded as a *symbolic* (not picturable)

representation of the intrinsically non-visualizable quantum state but, notice, still a representation of something *real*.

- (9) *Quantum completeness*: A complete description of the state of a quantum system S means that the state is represented by a *non-degenerate* state vector, that is, when there is only one state vector corresponding to any possible eigenvalue resulting from measurement on S . Or more formally, $|\psi\rangle$ is complete if $|\psi\rangle$ is defined in a state space spanned by eigenvectors of a *maximal set of commuting operators* $M = \{\hat{A}, \hat{B}, \hat{C}, \dots\}_{Max}$ corresponding to observables defined for S , *maximality* of M just meaning that the addition of any single operator to M results in a non-commuting set of operators.

Comment: Equivalent to this is the statement that all observables are fully represented by self-adjoint operators. The *hidden variables* of hidden variable theories (see below), on the other hand, are exactly physical variables which are *not* represented by self-adjoint operators so that the state vector is not seen as a complete representation of the physical state in hidden variables theories (Bohm and Hiley 1993; Auletta 2000 Chap. 32). So the quantum realist assertion of the essential completeness of quantum mechanics is the denial of hidden variables, not the statement that physics is completed.

- (10) *Quantum objectivity*: In quantum physics, no interaction-free observation or description (by way of at least preparation) is possible according to the very nature of the theory. An objective description accordingly includes the interaction of the system with all other systems in so far as these systems are part of the quantum-description (by way of entanglement) and with the whole measurement setup: *contextuality of quantum measurement* (Bohr 1949). This holds for the description of states and for the measurement of observables, respectively.

Comment: This is again very different from what *objectivity* means in classical physics. From a quantum realist perspective, however, the physical world is governed by $\hbar$ (cf. (4)) and interactions

are theoretically, not just practically, non-eliminable when we are investigating a physical system. Taking the theory seriously, thus, means to accept the interactions as part and parcel of the phenomena to be investigated and integrated in the very description of the phenomena. So objectivity here rather means *including*, not *excluding*, the interactions in the description (Bohr 1949). In this sense, quantum mechanics may be seen as a *theory of interactions* rather than as a theory of independent, interaction-free substances.

- (11) *Quantum realism*: *Physical systems* (a) exist objectively, that is, independently of any (physical) description and of any consciousness, and (b) they always exist objectively in definite *quantum states* (exception: subsystems in entangled states, but pure states exist for the whole system). Therefore, (c) definite *values* never exist for all observables but at best for a set of observables corresponding to a maximal set of commuting operators. (d) $\hbar$ lays at the basis of the whole conceptual structure and so *the quantum of action* has objective existence.

Comment: This again is a concrete implementation of scheme (R) but of course in terms of quite another physical ontology than is classical realism. The specific features again are contained in items (b) and (c) corresponding to the radical nonclassical state-observable structure in quantum mechanics, namely, (1) and (2) above.

Outlook and Alternatives

Of course, it might be tempting to try avoiding this kind of quantum realism. However, there is no easy way out if one wants to be true to what the experiments say.

It might be tempting to try denying that quantum mechanics deals with *individual systems* and opt for a *statistical ensemble theory*. Then, of course, the strange features like value-indefiniteness, superposition, and entanglement are just properties of ensembles and not the individual systems. But this does not account for the 2-slit experiment and other experiments which

may be made on individual systems (at a time). In general, ensemble theories are either quite unclear with regard to the individual systems, or they have to say that there are differences between individual systems in the same quantum state and in that case, they just degenerate to hidden variable theories without explicit specification of the hidden variables (Home and Whitaker 1992).

It might be tempting to try denying that quantum mechanics gives a *complete description* of the individual systems and so opt for the existence of *hidden variables*, that is, variables not represented by operators and so not part of the quantum description of states. There are, however, several no-go theorems severely constraining the nature of such hidden variables, showing that they have to be both *nonlocal* (allowing superluminal causal interactions) and *contextual* (values of different observables not being independent of each other). Hence, the advertised intelligibility typically disappears on closer inspection (Auletta 2000, Chap. 32; Cushing et al. 1995). The most popular variant, Bohmian mechanics, may look plausible as long as the focus is on the nice drawings of continuous particle tracks (Bohm and Hiley 1993, pp. 33, 53, 76), but such particle tracks are brought in at the expense of a multidimensional, nonlocal “guiding field” which has all the features of a pure ghost field. It carries no energy, has no sources, but nonetheless instantaneously and distance-independently guides the particles without being acted on by the particles, and it is only defined in an N -dimensional configuration space ($N \gg 3$). Nevertheless, it has to be assumed real if the Bohmian theory is to be understood at all realistically (Holland 1993, pp. 278–279). If a realist understanding of the guiding field is given up, a realist understanding of Bohm’s theory is given up – and if so, why bother with the hidden variables?

It might be tempting to try giving up the assumption of *measurement collapse* and so to try applying standard quantum mechanics to macroscopic bodies and measurement devices (so-called *Non-collapse theories*). However, the so-called *Decoherence theories* actually do not solve the problem of accounting for the

emergence of definite values in the classical domain (Schlosshauer 2007) and the attempt to simply accept the unrestricted superposition principle for macroscopic bodies, including ourselves and our measurement devices, as in the different variants of the *Many-world theories* are certainly not less bizarre than is standard quantum mechanics. (For the many faces of *Many-worlds* cf. (Barrett 1999), and for some of the technical problems cf. (Jaeger 2009, p. 139f)).

Then of course, *realism* may itself be given up, but this seems just to give up trying to understand the physical world at all. In short, it is difficult not to admit that the micro-world has very strange features from a human perspective.

As for connections to religion there have certainly been attempts to solve the quantum perplexities by introducing God and divine intervention (Baggott 2004, p. 257f.), but most people would see this as a clear instance of *obscurum per obscurum*, and the same goes for the several attempts of invoking eastern wisdom here (Stenger 1995, Chap. 1). A more promising link might be to see the micro-world as a great “other,” trying to tell us something very important and strange about the world and our place in it – in a nonpictorial language that we must struggle to understand.

Description

In contemporary academia, *Classics* is an umbrella term that refers to an interdisciplinary field of study, unified by its focus on the world of ancient Greece and Rome from prehistory to late antiquity. And because the Greco-Roman culture had such a far-reaching sphere of influence through trade and conquest, study of any of the early Mediterranean civilizations, such as that of Persia, Egypt, Israel, and so on, might also be considered as fitting under the *Classics* umbrella. Within this broad field, a wide range of disciplines intersect: anthropology, history, archaeology, philology, literature, art, linguistics, and many others. Each discipline employs its own methodology and perspective even though the evidence being studied from one discipline to another remains the same – artifacts such as manuscripts, inscriptions, works of art, architecture, and other material remains of these ancient cultures. Successful scholarship in the field almost always requires knowledge of ancient languages and literatures, particularly classical Greek and Latin.

Study of the *Classics* has long been intertwined with the concept of education in the Western tradition and so has been seen as studying the origins of Western culture. In fact, it could be considered the oldest of the academic

disciplines, being the forerunner of the modern ► **Humanities**. The concept of the *Classics* began with the ancient Greeks and Romans themselves, who educated their future citizens by having students imitate great works of literature. This practice was intended to teach rhetoric, grammar, ethics, aesthetics, and the best elements of culture from one generation to the next. Classical scholars began compiling lists of the works worthy of being imitated and discussing criteria for the assessment of such works. Although such lists varied from one individual to another, the practice developed into the concept of the canon, the “standard” works of literature, history, and philosophy identified as being those with which any educated person would be familiar. Even though the individual works identified as canonical changed, belief in the value of a classical canon to provide an educational foundation persisted.

This concept of the classical canon influenced Western European education for centuries, long after the time when the classical languages of Latin and Greek ceased common usage. In the Middle Ages, a formal education began when children first learned Latin through the imitation of selected classical works of literature, history, and philosophy. Then, institutions of higher learning used a Christianized canon to teach rhetoric, grammar, and logic, the foundation necessary for any advanced study. With the spread of humanism during the Renaissance, knowledge of classical texts expanded beyond medieval Christian boundaries, and application of classical concepts appeared in everyday life, including education. So classical authors and their concepts of a literary canon shaped the educational practices of the European Renaissance. Study of the classical canon of texts, along with the classical Latin and Greek languages, remained the foundation of Western European education until the rise of the modern university system.

By the nineteenth century, the new discoveries and the development of new methodologies that accompanied the creation of modern academic disciplines had remodeled the Western tradition of education. It had also expanded the definition of the field of *Classics* beyond studying classical languages and a specific canon of literature to

include the study of objects of art, politics, religion, archaeology, and myriad other facets of classical civilization.

The etymology of the term *Classics* explains why this field of study has been so valued in the past as well as why its influence appears to be currently declining. In its original usage, *classic* indicated socioeconomic status. The *classici* were the ancient Romans in the top socioeconomic classes, the opposite of the *proletarii*, who were in the lowest. Then, in the second century C.E., the Roman author Aulus Gellius applied the judgment of *classic* to literature, distinguishing a *scriptor classicus*, a writer of high quality, from a *scriptor proletarius*, or a writer of common quality (Sandys 1988, p. 200). For Gellius, the determining feature of a *scriptor classicus* was that it provided a model worthy of being followed, and his terminology implied a connection to the highest level of socioeconomic status. Studying the canon, studying the “best” works, was a practice of the upper class, and the judgment of the works included in the canon, the “best” works to study, arose from the values of the upper class.

And to identify something as a *classic* today still attaches the connotation of having a valued social status. In the postmodern, international world of the early twenty-first century, such value is increasingly questioned rather than merely accepted as it was in previous generations. Thus study of the *Classics* is increasingly becoming marginalized. Classical Latin and Greek are no longer widely taught in public school systems. The once-mandatory classical canon has been replaced with canons reflecting the modern nationalism of individual countries. Classicists today face the challenge of justifying the value of their work in the modern world, an ironic situation at a time when new technologies and archaeological discoveries are exponentially increasing their knowledge of the ancient world.

Self-Identification

Science

The *Classics* is defined by subject matter and purpose of understanding classical Greek and

Roman civilization. It is possible, though, for an individual topic being researched with the empirical methodology of a science to fall within the Classics paradigm if the subject matter and purpose of the research are appropriate.

Religion

Religion may be a discipline of study contained within the *Classics* paradigm. Understanding the various religious practices and beliefs of the classical era helps *Classics* scholars understand the literary and philosophical texts of that time. In addition, scholars interested in the modern discipline of religion frequently find knowledge of the *Classics* essential because that era shaped the development of the world's major religions – Islam, Judaism, and Christianity – as well as some of the less widely practiced religions.

Characteristics

Study of the modern *Classics* is distinct among other disciplines because its existence relies on the interaction between a variety of disciplines in order to understand the ancient civilizations of Greece and Rome. Its focus on understanding the past is similar to several other individual disciplines. History concerns itself with cause and effect as it attempts to reconstruct the order of human events. Anthropology studies the beliefs, practices, and cultures of living human beings while archaeology studies human culture by examining the material remains of human beings. Philology is the study of language and literature. The *Classics* relies on all of these disciplines as it focuses on creating as complete an understanding as possible of the culture of a specific time period and geographic location.

Relevance to Science and Religion

Study of the *Classics* is relevant to “Science and Religion” because it reveals the philosophical and/or historical foundation for contemporary Western concepts and practices in both

science and religion. In addition, study of the *Classics* reveals the differences between the perspectives of the ancient and modern worlds. The basic conceptual category of “science” as it is understood in modern times was not used in the classical era, even though many of the subject areas and methodologies now considered to belong to “science” were being developed and explored during that time. Perception of the conceptual divide between the ancient and modern worlds allows an intellectual distancing from modern assumptions and so encourages a critical examination of modern understanding.

Sources of Authority

The most authoritative source in the study of the *Classics* is primary source material. Because such a vast period of time exists between the modern and the classical world, scholars must rely first on the only objective information available, primary source material, rather than relying on prior interpretations of that information to build knowledge.

Another type of authoritative source is found in the classical canon; the selection of Greek and Latin works judged to possess the most merit and so considered to have been influential in shaping Western culture. The fact that the canon is primary source material selected to reflect a particular set of values can make it problematic to use in understanding the classical world because every era has identified its own canon. Careful attention must be given to who has made the judgments about the works included. For example, relying on fifteenth century selections to understand life in first century Rome must be suspect. And yet if the canonical decisions being examined were made in the first century, then they reflect significant insights into the values of that time. The canon is usually more relevant to understanding recent eras than classical ones because it gives insights into how a particular time period interpreted the classical authors and objects of art judged to be worthy of study in that time.

Ethical Principles

The ethical principle guiding study in the *Classics* is remaining as true as possible to the primary source material. Knowledge of a broad range of source material – archaeological evidence, objects of art, literary/philosophical/historical texts – is essential as well to ensure understanding the source within the context of its own time period. This also necessitates knowledge of a range of interacting disciplines and methodologies, such as literature with skills in textual analysis, philology with skills in translation, philosophy with knowledge of philosophical argument, archaeology with the use of statistics, and so on.

Key Values

Study of the *Classics* demands respect for the culture of classical Greece and Rome, as well as the belief that this culture is relevant to present and future civilization. This relevance might come from the direct influence and/or knowledge of classical traditions and values in the present culture or it might come from the interaction of previous historical eras with the classical culture. In addition, *Classics* scholars work directly with primary materials from the classical era, so direct knowledge of the ancient languages and cultures is important. New discoveries are regular, and so the field is constantly growing. Finally, because the *Classics* is an interdisciplinary field, the constant interaction between disciplines requires openness and responsiveness to a variety of methodologies and conclusions of a range of perspectives.

Conceptualization

Because the *Classics* exists at the intersection of a variety of disciplines, defining these terms depends on the individual perspective being applied at any specific time. For example, in one context, a term might carry the meaning used during the classical era, while in another context, the term might carry a modern disciplinary

perspective. So identifying a single definition for each term is not possible.

Clinical Neurophysiology

Paolo M. Rossini
Catholic University, Policlinic A. Gemelli,
Rome, Italy

Description

Today clinical neurophysiology (CN) is mainly devoted to diagnosis and objective measures for the clinical syndromes caused by diseases affecting the *brain*, *spinal cord*, *peripheral nerves* (*electroneurography*, *ENG*), and *skeletal muscles* (*electromyography*, *EMG*). History of modern CN is usually dated back to the discovery of the electroencephalogram (EEG) and its clinical applications by the German scientist Hans Berger (1873–1941) between 1920 and 1930. Immediately before and after World War II, neurophysiological techniques devoted to the study of muscle fibers and peripheral nerves by Lord Adrian in UK and Fritz Buchtal in Denmark enlarged the scenario of modern clinical neurophysiology. More recently (from mid-1970s), techniques able to capture selective brain and spinal cord signals in response to specific stimuli, as well as able to identify brain responses to cognitive tasks were acquired under the heading of *stimulus-related* and *event-related evoked potentials*. Since the 1980s, techniques for non-invasive electric and magnetic transcranial brain stimulation have been introduced. During the same year, Sam Williamson & Collaborators introduced modern sensors to capture the

magnetic counterpart of the EEG called magnetoencephalography (MEG).

Particularly in Scandinavian countries (but now also in UK, Italy, Spain, and many other countries) CN progressively became a discipline of its own, being treated as a separate entity from *Neurology* even if in several countries it is still regarded as part of neurological specialty (i.e., Germany).

Modern EEG aims at clinical evaluation of epileptic syndromes, sleep disturbances, comatous states (with the impelling discrimination between a “brain death” and “brain vegetative” conditions, a prerequisite for organs donation); MEG is mainly employed in neuroscientific research and in presurgical localization of high-risk brain centers (i.e., language) for drug-resistant epilepsy undergoing neurosurgical procedures; EMG and ENG help in diagnosing peripheral nerves and muscles disease, while TMS helps in evaluating brain excitability and corticospinal fibers conductivity in multiple sclerosis and spinal cord diseases, as well as in following up brain plastic reorganization following a traumatic or vascular (i.e., stroke) lesion.

Self-Identification

Science

CN has followed the track of basic research in neurophysiology as a natural science. It sees itself as a scientific instrument to enhance knowledge about the pathophysiology of the human [► nervous system](#) and the related musculature. In a clinical context, it has been progressively used as an extension and refinement of the neurological examination, being able to provide objective measurements as well as to unveil abnormalities in a preclinical state (i.e., before a neurological disease is provoking symptoms). Correlations between electrophysiological abnormalities and structural damage were developed in decades following the introduction of computerized tomography and of magnetic resonance imaging of the brain allowing to test in vivo the presence, nature, and extension of the lesion.

In line with neurology, CN applies the scientific methods of the natural sciences for clinical

and basic research as well as for diagnostic procedures. For instance, CN definitely established a causative relationship with the generalized or localized presence of transient paroxysms in the EEG like spikes, spike-and-waves, and alpha depression and various types of epilepsies, and to understand that sleep is not a simple and continuous state, but is the result of a complex pattern of micro-states which develop according to a well-defined hierarchy during the hours separating falling asleep from awakenings.

More recently, neurophysiological parameters were integrated with information from techniques investigating brain function by measuring local blood flow and metabolism (i.e., oxygen and glucose consumption) as well as production of neurotransmitters as in *functional MRI and positron emission tomography (PET)*. International CN is governed since 1949 by the International Federation of CN (IFCN) to which more than 50 national societies are affiliated. IFCN – on its own – is divided into geographical chapters (i.e., European, Latino-American). IFCN has a scientific journal with an about 60-year long tradition, originally entitled *Electroencephalography & Clinical Neurophysiology* and recently renamed *Clinical Neurophysiology*.

Characteristics

CN is mainly dealing with function of brain, spinal cord, peripheral nerves, and muscles as reflected by their electromagnetic spontaneous or stimulus-related activities. Moreover, CN aims to establish a strong relationship between clinical symptoms on one side and the topography of lesion on the other. Symptoms – broadly speaking – include movement deficits, abnormalities in sensory perception/processing, cognitive abnormalities (i.e., memory disturbances). Neurophysiological recordings *in the presence* of such symptoms (particularly when they are transient) help in identifying which is the neural network affected. In fact, once a lesion has been established, it can produce symptoms due to the neural tissue directly damaged, but also from the indirect effects at distance in all the relays

connected with the damaged area, even if they are structurally healthy. This is an important concept which helps understanding how CN can nicely integrate techniques which only evaluate brain structure and not function.

Relevance to Science and Religion

CN is sometimes touching areas relevant to a religious view of life, particularly when it is employed to find out a “sign of death” to define the end of life of a living person. The most universally accepted instrumental parameters for “brain death” definition are nowadays the complete lack of any EEG activity and the absence of any vital sign from the brain stem (an area controlling autonomic life including heart rate, respiration, blood pressure, etc.).

Sources of Authority

Since its beginning, CN has been quite close to human basic physiology on one side and to clinical neurology on the other. Along the neurophysiological tradition, there are a number of Nobel Prizes (i.e., Adrian for neuronal excitation mechanisms), excellent physiologists (i.e., Moruzzi & Magoun for sleep mechanisms), and outstanding clinicians (i.e., Gastaut for epilepsy). More recently, Guidelines & Recommendations regularly published by IFCN, Handbooks of CN, and – most important – the official organ of the Federation the journal *Clinical Neurophysiology* represent a first line of authoritative information and sources of references for doctors and technicians working in the field of CN

Along the history of this specialty, the group of Pisa (Giuseppe Moruzzi) was the frontline world place for the study of sleep mechanisms, the team of Marseille (Henry Gastaut) was a center of excellence for epilepsy in the 1950s and 1960s, the University of London was a reference place for Evoked Potentials (Martin Halliday who recently disappeared), the research group in Iowa City (Jun Kimura) was following the pioneering studies of Buchthal in Copenhagen on electromyography and reflexes.

Ethical Principles

As for every medical discipline, CN follows the rules of the “Hippocratic Oath,” i.e., a set of ethical principles for the medical community regarding the care and treatment of patients which were developed by the ancient Greek physician Hippocrates, and the more recent lines of the Declaration of Helsinki of 1971 which is a set of ethical principles for the medical community regarding studies with human beings. The declaration was developed by the World Medical Association, as well as of the Good Medical Practice as requested by the European Union.

Key Values

Along the vein of the “mother discipline” of neurology the key values of CN is helping to diagnose and treat properly symptoms and deficits due to ► [nervous system](#) and muscles diseases, finally ending in physical, mental, and cognitive/behavioral impairments.

Conceptualization

Nature/World

The field of such conceptualization is – for CN – restricted to the human being which is approached within the frame of the types and patterns of electromagnetic activities that the living brain, spinal cord, nerves, and muscles are producing throughout life (including maturation and aging). The “world” is only conceptualized either as a micro-environment (namely the one within or around the individual neuronal cell and its prolongations and contacts) or as a macro-environment, that is, the physical space within which the patient is living.

Human Being

As previously stated, all the basic and highly sophisticated functions of the nervous systems and muscles are conceptualized within a frame taking into account their electromagnetic counterpart.

Life and Death

Life is conceptualized as the presence of brain activity as measurable via EEG and evoked potentials recordings, particularly for those signals originating from the brain stem. Lack of such activity for a prolonged period of time (i.e., 6 or 12 h according to different national legislations) leads to the definition of “► [brain death](#).”

Reality

Reality is considered the physical world (external, outside the body, and internal to the body, i.e., visceral activity) in direct contact with the nervous system through senses.

Knowledge

Learning and knowledge is now seen as a complex mechanism of transient (minutes or hours) or prolonged (months and years) modifications of synaptic contacts and neuronal wiring leading to storage of physical, educational, and emotional experiences. This is based on cellular mechanisms named after the Nobel Prize Eric Kandel, *Long-Term Potentiation and Depression* (together with the genetic and proteic and biochemical changes combined to them) and can be represented as a dynamic process (probably consolidated by certain function of night sleep) continuously evolving from birth to death.

Truth

Truth is conceptualized as the scientific validity of a theory which has usually a midlife of 5–10 years, with the exception of some basic concepts including those for cellular excitability.

Perception

Perception can be *conscious, preconscious, and unconscious*; modern techniques of CN (particularly event-related potentials) help in classifying. Perception is usually linked to one of the five senses or – more frequently – is an amalgam of multisensory and emotional matrix which makes perception an exquisitely individualized experience, still within the frame of a general world.

Time

Time is a brain category aiming to classify modifications in the physical world (external and internal) as well as the human feelings related or combined to such changes.

Consciousness

Consciousness is the ability to voluntarily perceive, classify, and eventually react to any physical stimulus in the outside or inside world. Different types and levels of consciousness can be defined either in normal (i.e., awake, drowsy, and sleeping states) or in pathological situations which affect transiently, acutely or progressively and steadily consciousness (i.e., epileptic attack, dementia, light or deep coma, vegetative comatous state, etc.).

Relevant Themes

Critical points within these concepts include the definition of the conceptualization of the *SELF* both in normal situations (i.e., in the newborn) and in brain diseases which steadily (i.e., in severe retardation, dementia, etc.) or transiently (i.e., epileptic attack, post-traumatic amnesia, transient global amnesia) affect the ability for sensory processing/classification, problem solving, and decision taking.

Clinical Psychology

Description

From a historical point of view, clinical psychology is a relatively young discipline that developed out of medicine, psychiatry, and philosophy at the end of the nineteenth century. Broadly speaking, it applies knowledge about psychological processes to the understanding, assessment, prevention, and treatment of psychological distress of individuals (children, adolescents, and adults), couples, families, and groups. Its history has been dominated by four major theoretical approaches: (a) psychoanalytic/psychodynamic, (b) learning/cognitive-behavioral, (c) humanistic/experiential, and (d) family and systems (Hersen and Gross 2008).

Although each of these four approaches encompasses a broad array of evolving theories and clinical applications, they each have a number of specific assumptions and foci that distinguish them from the other theoretical approaches. The psychoanalytic approach, which originated in the work of Freud, mainly focuses on the role of psychological conflict, the importance of unconscious factors, and the complex ways early development influences psychological functioning across the life span. The learning/cognitive-behavioral approach focuses primarily on learning processes and how these give rise to cognitive-affective schemas that influence our perceptions and behavior. Humanistic/experiential approaches center on an understanding of the whole person and the self-actualizing tendencies and potentialities within each person. Family and systems approaches focus on the complex interactional processes within couples and families and how these determine the functioning of the individual, couple, and family.

Within each of these approaches, interventions have been developed that are still widely practiced today and that have been the subject of systematic treatment evaluation in both controlled and naturalistic research (Lambert 2004). This includes, for example, long-term and brief psychoanalytic psychotherapy (psychoanalytic approach); (cognitive-) behavioral, dialectical, and more recently mindfulness-based therapy

(learning/cognitive-behavioral approach); client-centered, gestalt, and humanistic therapy (humanistic tradition); and family and couple therapy (family/systems tradition). The continuing influence of these four theoretical approaches is also exemplified by the fact that major figures within these approaches are among the most famous and most cited psychologists, including Sigmund Freud and Erik Erikson (psychoanalytic tradition), Burrhus F. Skinner and Hans J. Eysenck (learning psychology), Carl Rogers (humanistic/experiential tradition), and Gregory Bateson and Paul Watzlawick (family/systems theory).

The last decades have witnessed clear integrative trends among these major theoretical approaches both in research and practice (Lambert 2004). For instance, many practitioners use insights, methods, and techniques from these various approaches in their clinical work. In this context, at least two forms of integration have been distinguished. First, there are clear trends toward *technical* integration, with practitioners from various orientations incorporating techniques used in other theoretical approaches. Second, there are increasing signs of *theoretical* integration with the aim of developing more encompassing and overarching theories about normal and disrupted psychological development. Both these trends have resulted in integrative “waves” within each tradition. Within the psychoanalytic tradition, for instance, there has been more attention to experiential, cognitive and behavioral aspects in human functioning, which also has led to the development of shorter, more focused treatments. Within the cognitive-behavioral tradition, in turn, there has been a growing openness for more dynamic, interpersonal, developmental, and experiential issues. Within the experiential and family/systems traditions in particular, ideas and techniques from both the psychoanalytic and cognitive-behavioral tradition have been widely incorporated.

Yet, integration between the various approaches continues to be hampered by various factors, not in the least because each of these major approaches has in part developed in reaction to (perceived) shortcomings of the other

theoretical approaches. Hence, each of the major theoretical approaches is based on partly incommensurable assumptions about human nature, normal and disrupted development, and the aims and nature of prevention and treatment strategies. Thus, currently, “assimilative integrationism” (Messer 1986), which means that concepts, hypotheses, and therapeutic techniques borrowed from other theoretical orientations are assimilated in a theoretically meaningful way in an existing theoretical framework, predominates. A truly integrative theoretical framework, therefore, is unlikely to emerge in the near future.

In addition, clinical psychology has made major contributions in the areas of assessment of both normal and disrupted psychological capacities and processes (e.g., intelligence, personality, neuropsychology, and psychopathology) and the classification of psychiatric disorders (Hersen 2008). More recently, the field has witnessed an important shift from a focus on psychopathology and its treatment to the prevention of psychopathology and behavioral problems and distress more generally (Lambert 2004). The fields of behavioral medicine and health psychology in particular have emerged as a strong force within clinical psychology, which has resulted in a substantial broadening of the scope of clinical psychology, encompassing so-called positive psychology (the scientific study of happiness and well-being), and interventions aimed at ameliorating quality of life and well-being in patients confronted with somatic disease and other health problems.

The future of the field of clinical psychology is difficult to predict as many scientific and extrascientific factors influence its course. As noted, integrative trends are likely to continue, but it seems highly unlikely that the field will reach a consensus soon with regard to the classification, assessment, and prevention/treatment of psychological problems, as major differences remain between the various theoretical approaches with respect to their views of human nature and, ultimately, their worldview. Other factors that are likely to determine the future of the field include the increasing influence and

pressure of managed care and economic considerations (e.g., concerning the cost-effectiveness of psychotherapy) as well as the growing dialogue and integration with the neurosciences. Finally, the rapidly expanding fields of behavioral medicine and health psychology, with psychologists being involved in increasingly broader domains, including the prevention of both physical and mental disease, are likely to transform clinical psychology as it exists today. The assimilation and integration of these influences are major challenges for the future of clinical psychology.

Self-identification

Science

Although clinical psychology self-identifies as a science, based on the rigorous empirical scrutiny of its theoretical assumptions, techniques, and methods (Kazdin 2003), there are important differences in this regard among the four major theoretical approaches. Without any doubt, the learning/cognitive-behavioral tradition identifies most strongly with the view of clinical psychology as a science. This tradition has been the strongest advocate of the so-called scientist-practitioner model, which stresses that practitioners should rigorously train in and apply scientific findings in the prevention and treatment of psychological problems. Thus, the learning/cognitive-behavioral tradition has strongly emphasized the value of the scientific model, as is also exemplified in the emphasis on the systematic evaluation of interventions, use of evidence-based techniques and methods, and, perhaps even more importantly, the view that the scientific model also provides a model for the prevention and treatment of psychological problems. Indeed, although some current models tend to adopt a somewhat different view, the cognitive-behavioral approach started from the assumption that patient and therapist should become involved in a so-called collaborative empiricist stance attempting to identify and then falsify particular beliefs and assumptions about

reality. Therefore, within this tradition, science is not only valued as a way of gaining knowledge but also provides a model for treatment.

Historically, psychodynamic, experiential, and family/systems approaches, although generally acknowledging the importance of science, tend to emphasize equally and sometimes perhaps more the importance of intuition and personal factors and qualities. Within these approaches, clinical psychology (and psychotherapy in particular) is seen not only as a science but also as an art. Or, perhaps better, it is seen as a profession that not only involves and is based in scientific knowledge but also necessitates specific personal qualities (such as empathy and psychological mindedness) as well as a personal growth process that involves learning from experience. Thus, for example, we see the emphasis in these approaches on extended and, to a certain extent, lifelong supervision and even personal therapy.

Although there is growing consensus in the field that clinical psychology is not a “pure science,” differences in opinion about the role and importance of the “science” versus “art” issue remain. These differences continue to lead to heated debate.

Religion

The relationship between (clinical) psychology and religion has been a troubled one ever since Freud's claim, in his seminal work *The Future of an Illusion*, that religion is an expression of infantile needs, a “childhood neurosis” (Freud 1927, p. 53), relegating religion and religious experiences more generally to the realm of illusion. This led psychoanalysts and subsequent clinical psychologists more generally to regard religion with suspicion and even disdain and associate religion with infantile longings for protection, omnipotence, and omniscience. This negative attitude was further reinforced by Freud's assertion that “The religions of mankind must be classed among the mass delusions” (Freud 1930, p. 81). Similarly, Albert Ellis (1960), one of the founding fathers of learning/cognitive-behavioral tradition, saw religion as

a set of irrational assumptions from which individuals had to be liberated.

In recent years, a more positive and even reconciliatory attitude toward religion has developed within clinical psychology. While psychologists and psychiatrists continue to be far less religious than their clients, most psychologists and psychiatrists have a positive attitude toward religious issues in clients. This is further exemplified by a more positive attitude and acceptance of religiosity and religious experiences as well as spirituality. This growing openness is also the result of a shift in what is currently conceived of as religion, specifically, a shift away from traditional, organized religion that is focused on the truth of religious beliefs, toward a more personal interpretation and experience of religion. Likewise, in psychoanalysis, there has been a growing appreciation of the realm of illusion. This can be traced back at least to Winnicott's (1953) work, particularly his work on the importance of transitional space. Similarly, within the cognitive-behavioral tradition, Eastern spiritual practices are increasingly incorporated and integrated in so-called mindfulness-based and acceptance and commitment-based treatments (Hayes et al. 2003). Moreover, the shift within religion and religiosity to a greater emphasis on personal experience, rather than an emphasis on organized religion and the endorsement of particular beliefs, has also fostered the dialogue with humanistic and experiential approaches within clinical psychology that always have had a greater openness toward spiritual issues and experiences. This is further reinforced by the growing role of qualitative approaches to research, often inspired by constructivism and critical theory, that focus much more on personal, intimate experiences and how these are shaped in part by cultural forces, including religion and spirituality.

Finally, the growing dialogue between religion and clinical psychology is also exemplified by the emergence of a so-called spiritual strategy, promoting the integration of religion and/or spirituality and psychotherapy. These proposals have ranged from the integration of traditional

Christian elements such as prayer and biblical exegesis or Eastern practices such as yoga and meditation with traditional forms of counseling and psychotherapy to the development of religious/spiritually inspired forms of psychotherapy. Findings that religion and spirituality are often positive for both physical and mental health, and that integrating religious/spiritual elements is associated with better treatment outcome, especially among religious clients, have further promoted these developments. Yet, criticism remains, arguing that clinical psychology as a science should remain neutral with regard to religious issues and should not strive to promote religious or spiritual beliefs.

Characteristics

Because of its focus on both normal and disrupted human development, clinical psychology has close ties with neighboring sciences and approaches, most notably psychiatry and other social sciences (e.g., sociology, philosophy, anthropology) and, to some extent, also religious and spiritual worldviews (Lambert 2004). Its strong focus on the importance and role of psychological processes in explaining normal and disrupted human development distinguishes clinical psychology from neighboring scientific approaches such as psychiatry (which focuses more on biological factors) or sociology (which focuses primarily on social factors). Yet, given our increasing knowledge of interactions among psychosocial and biological factors, the boundaries between these various scientific disciplines are increasingly becoming blurred. The future is likely to witness the emergence of a more integrative science of human behavior.

The focus on psychological factors distinguishes clinical psychology from religious and spiritual traditions as it studies the role of psychological factors within religion/spirituality but does not attempt to explain (or explain away) religion and spirituality as such nor does it attempt to offer a consistent worldview ("Weltanschauung").

Relevance to Science and Religion

Clinical psychology has always had a vivid interest in the science-religion debate. In some respects, (clinical) psychology originated from what was conceived as a need for emancipation from religious views and explanations, particularly concerning so-called abnormal behavior, replacing religious explanations with psychological explanations of these phenomena. For instance, behaviors that were seen as an expression of possession by evil forces such as the devil or the result of sinful behavior were explained in psychological terms (e.g., projection, wish fulfillment). Moreover, psychological explanations were invoked to explain the origin of religious/spiritual explanations and religion/spirituality itself. As noted, Freud's theories about religion as reflecting the human need for certainty and control over the forces of nature (Freud 1927, 1930) and Ellis's views of religious belief as a set of irrational attitudes that provide a false sense of control and purpose in life (Ellis 1960) are cases in point. In general, historically, clinical psychology has been very critical of religious/spiritual beliefs, largely reducing them to psychological needs for certainty, control, and purpose in life. Yet, paradoxically, there have always been more favorable views of religion within clinical psychology, particularly within humanistic approaches. Finally, clinical psychology has largely abandoned attempts to explain the origins of religion; it currently focuses mainly on the role of psychological processes in religion and religious behavior rather than attempting to explain religion as such.

Sources of Authority

Major sources of authority include seminal figures that have played a key role in the development of clinical psychology, many of which are still among the most highly cited psychologists, including Sigmund Freud, Burrhus F. Skinner, Hans J. Eysenck, Ivan Pavlov, Carl Rogers, Paul Watzlawick, and Aaron Beck, to name only a few. Their influence can still be felt nowadays

and continues to influence the field. Also, the scientific method, particularly the strong dedication to quantitative research and statistics from a neopositivistic perspective, is an important source of authority (Kazdin 2003). More recently, the importance of qualitative methods and narrative and constructivist approaches is increasingly recognized. These lead to more relativistic, constructivistic view of scientific knowledge rather than the neopositivist correspondence view of the relationship between scientific knowledge and reality that dominated much of clinical psychology in the past.

Authoritative journals, evidenced by their high impact factor, include *Annual Review of Clinical Psychology*, *Clinical Psychology Review*, *Development and Psychopathology*, *Journal of Child Psychology and Psychiatry*, *Journal of Abnormal Psychology*, *Journal of Consulting and Clinical Psychology*, *Journal of Abnormal Child Psychology*, *Neuropsychology Review*, and *Psychological Medicine*.

Ethical Principles

Despite obvious differences in the worldview and view of human nature underlying the different theoretical approaches within clinical psychology, there has been a remarkable agreement on the basic ethical principles guiding the discipline across these theoretical approaches. The American Psychological Association Ethical Principles and Code of Conduct, for instance, specifies the following ethical principles that are largely shared by all clinical psychologists: (a) beneficence and nonmaleficence, (b) fidelity and responsibility, (c) integrity, (d) justice, and (e) respect for people's rights and dignity. Moreover, as a profession, clinical psychology has invested much effort in the development, dissemination, and use of ethical guidelines in the conduct of research and the practice of clinical psychology.

Key Values

In agreement with its ethical principles, these include respect and openness for the person's

rights and dignity (e.g., concerning gender orientation, spiritual/religious beliefs, values), trust, integrity, and the attainment of a satisfying balance between autonomy (e.g., individuation) and relatedness (e.g., the capacity to attach to others in meaningful ways), enabling individuals a greater sense of internal freedom and satisfaction with life. In this context, clinical psychology generally promotes a benevolent neutrality toward religious/spiritual issues, leaving it to the individual whether he or she wants to pursue or not a spiritual/religious path in life.

Conceptualization

Nature/World

Nature and world are not only or merely conceptualized as preexisting, biological realities but also partly as sociocultural and psychological constructions.

Human Being

The major theoretical approaches have had very different concepts of what it is to be a human being. From a traditional psychoanalytic point of view, human beings are seen as intrinsically characterized by conflicts between desires, wishes, and impulses on the one hand and the exigencies of external reality, initially represented by attachment figures which are increasingly internalized, on the other. Learning and cognitive-behavioral approaches see human beings primarily in terms of experience-expectant information processing systems. Humanistic/experiential approaches primarily conceptualize human beings in terms of self-actualizing potentialities. Family/systems approaches, finally, consider human being's role and position within broader systems, such as the couple, family, and society, emphasizing less the individuality of the person, but seeing persons as influenced by and playing a role in complex dynamics and laws involved in systems.

Life and Death

Life and death are considered to be fundamental coordinates that human beings have to confront.

Clinical psychology has documented how coming to terms with issues such as mortality and death characterizes the human condition and may lead to considerable distress (e.g., narcissistic denial of mortality by vigorously pursuing power and status, feelings of depression). The psychoanalyst Erik Erikson was among the first to conceptualize this process of coming to terms with life and death. He pointed out that unsuccessfully working through these issues can lead to despair, whereas coming to terms with them is associated with feelings of integrity, i.e., the sense that one's life has had a meaning and that one has contributed not only to one's own life but also to the life of significant others such as a partner, children, and society more generally. Such integrity also involves the acceptance of death as an inevitable part of life.

Reality

Within clinical psychology, various conceptions of reality coexist. They range from a correspondence view of reality (i.e., that science discovers reality and truth and thus assumes that scientific knowledge corresponds to reality) to views that see reality as a construction based on meaning-making processes. There are different positions between these two extreme poles. Within this context, the various theoretical approaches within clinical psychology have been influenced by different philosophical schools of thought. However, they have rarely made explicit their own assumptions with regard to the nature of reality and its relationship to the science of clinical psychology, despite the obvious importance of such issues (e.g., with regard to the nature of intelligence, the distinction between "normality" and psychopathology, or "abnormal" sexuality). Although several movements, including anti-psychiatry and feminism, have questioned many assumptions of clinical psychology about reality, currently these issues seem to have disappeared into the background even though they occasionally reemerge.

Knowledge

Clinical psychology sees knowledge as the result of a complex learning process in which both trial and error and insight play a considerable role.

Although some approaches have tended to consider knowledge and its application in isolation, developmental clinical psychology has clearly shown that knowledge first and foremost develops in an interpersonal matrix and thus is intimately tied to the development of social cognition and interpersonal relationships (Fonagy et al. 2007).

Truth

As in any science, clinical psychology has been dominated by a search for truth based on a correspondence versus consensus view of the relationship between scientific knowledge and reality/truth. Also, the major therapeutic approaches derived within clinical psychology all include to a considerable degree a search for truth. In this respect, searching for truth is either conceived as a search for truth in the sense of reconstructing one's past and factors that have influenced one's life course as they have really happened ("historical truth") or what is true for the individual regardless of historical truth ("narrative truth") (Spence 1982) or a combination of these two positions.

Perception

Clinical psychology has contributed in important ways to our understanding of perception as influenced by expectations which in turn are the result of experiences and interactions that have been internalized over time as internal working models or cognitive-affective schemas. Although on the positive side, these schemas bring order to our perception of reality, make reality more predictable, and thus prevent the individual from being overwhelmed by information, they also have the potential to bias or distort our perception in important ways.

Time

Time is an important concept within clinical psychology. Almost every psychological process or capacity develops over time and is constantly subject to change across time (e.g., memory, personality, intelligence). Moreover, several psychological processes seem to be intimately related to time. An episode of depression, for

example, appears to spontaneously disappear with the passing of time in many depressed individuals. Similarly, the process of mourning takes time. Related to this, clinical psychology has also pointed to a distinction between objective and subjective time, i.e., time as it is experienced by individuals. Subjective time can be influenced by many factors, such as mood and fatigue. For example, depressed individuals often experience a slowing of time to the extent that some feel "frozen in time." Likewise, psychotic disorders may seriously disturb the experience of time. As most psychological capacities, the capacity to experience time and to envision oneself in the past, present, and future develops across the life span, and several psychological disturbances may perturb this capacity.

Consciousness

The role of consciousness has been a matter of great debate within clinical psychology. Whereas some, such as the early behaviorists, considered consciousness as a mere epiphenomenon with little or no influence on behavior, other traditions, such as the phenomenological and humanistic, considered consciousness to be a central causative factor in explaining human behavior. Still other traditions, such as the psychoanalytic approach, saw consciousness as only a small, though not negligible, aspect of human psychological functioning, putting the priority on unconscious psychological processes. Currently, there is an emerging consensus not only that many psychological processes that determine behavior are unconscious (i.e., happen outside the individual's awareness) but also that consciousness and particularly the ability to reflect on one's own internal mental states (mentalization) are equally important determinants of behavior. Also, emerging is consensus that the capacity for reflective functioning may play a key role in distinguishing human beings from nonhuman primates and other animals (Fonagy et al. 2007).

Rationality/Reason

Congruent with the different emphasis on science in the major theoretical approaches, the different traditions in clinical psychology show clear

differences in their attitudes toward and valuing of rationality and reason. Within the learning/cognitive-behavioral tradition, rationality and reason are most strongly emphasized, whereas in the other theoretical approaches, the limits of rationality and reason are more clearly acknowledged and embraced.

Mystery

Because clinical psychology partly emerged as a reaction against religious/spiritual explanations, striving to develop into a strong science, there has been a clear tendency toward demystification in clinical psychology. Because of this, with some important exceptions, the implicit assumption that all of human behavior could be explained in terms of psychological (e.g., wishes) and/or biological (e.g., activation of neural circuits) processes has dominated clinical psychological research and practice. Thus, for instance, belief in ghosts and, in a similar vein, religion and mystical/spiritual experiences is explained in terms of anxious expectations, wish fulfillments, and/or antedated modes of thinking and experiencing reality, for example, omnipotence of thought or projection. Although there always has been a countermovement arguing for the limitations of psychological explanations in explaining the mysterious (e.g., the meaning of life, “religious” or “spiritual” experiences, beliefs about life after death), congruent with its scientific stance, the assumption that all experiences can be explained by laws governing psychological processes dominates clinical psychology.

Clock Gene

Jörg-Peter Ewert

Faculty of Natural Sciences, University of Kassel, Schauenburg, Germany

It is suggested that clock genes are involved in autoregulatory transcription/translation-based feedback loops which turn these genes on and off in a circadian cycle of about 24 h.

The mammalian *per* genes are rhythmically expressed and their proteins PER are found within “clock cells” of the suprachiasmatic nucleus, SCN, the central circadian pacemaker in mammals. The SCN, located in the ventral anterior hypothalamus, obtains retinal input and drives the rhythmic secretion of the hormone melatonin in the pineal gland. This hormone communicates the circadian timekeeper’s information to various parts of the body. Mammalian photoreceptors, too, contain the circadian pacemaker. However, findings suggest that PER1 proteins play roles in the retina different from those established in the SCN.

[Cognition](#); [Cognitive processes](#)

Description

Cognitive psychology is concerned with the scientific study of the mind. As a branch of

experimental psychology, cognitive psychology utilizes experimentation to study such topics as attention, memory, perception, language, and reasoning. The term “cognitive psychology” was first introduced by Ulric Neisser in his 1967 book, *Cognitive Psychology*. At the time, cognitive psychology partly arose as an alternative to behaviorism, which had denied that internal mental states can be studied scientifically. Because mental processes are not themselves directly observable, behaviorism focused strictly on stimulus–response associations, without theoretical consideration of the mental processes that occur in between. Unlike the behaviorists, cognitive psychologists assume that mental processes can (and should) be studied scientifically.

Several factors contributed to the emergence of cognitive psychology as a discipline. Among them was World War II’s contribution to the military need for understanding cognitive processes. Another contributing factor was the advent of the computer, which provided a useful metaphor for theorizing about mental processes at several levels, including the notion of representation, information processing, and the distinction between hardware and software.

Cognitive psychologists often use a factory example to illustrate what cognitive psychologists do. The example is as follows: *One is observing a factory, trying to determine what goes on inside. Trucks deliver supplies at one end, while different trucks pick up finished products at the other. The only method available for determining what goes on in the factory is to manipulate the shipment of supplies then carefully observe what comes out at the other end. The mind can be viewed in a similar fashion. Cognitive psychologists want to know what goes on inside of it, but cannot actually see its inner activities. They can, however, examine what goes in and what comes out and can experimentally manipulate what goes in, examining what comes out, to test hypotheses about what occurs inside.* Cognitive psychologists, therefore, are very concerned with experimentation and theory. Experiments are conducted to examine cognitive processes, and theories of those processes are

developed, tested, and modified or discarded accordingly.

A classic issue in cognitive psychology concerns visual imagery: Do people form images in their minds that are pictorial analogs to their real-world counterparts? Shepherd and Metzler’s (1971) now-classic study of mental rotation examined this by presenting participants with three-dimensional shapes on a screen. Sometimes the shape on the right was different from the shape on the left. Other times, the shape on the right was identical to the shape on the left and merely rotated somewhat from the position on the left. Participants’ task was to determine if a given pair of shapes was identical (and just rotated differently in space) or different. The hypothesis was that participants perform the task by forming a mental image of the two shapes, then mentally rotating one of the shapes until it reaches the same position as the other to determine if they are the same. In support of this idea, when the two items were identical, participants’ reaction times to press a button indicating so increased linearly with the degrees of rotation from the left figure to the right. In short, the more a shape needed rotating to match its neighbor’s position, the longer it took people to recognize that the two were identical. This is a good example of manipulating what goes into the system, examining what comes out of the system, and making inferences about what must be going in within the system.

Recent developments in cognitive psychology are many. It is a rapidly growing field with many domains of research (e.g., attention, memory, language) and many real-life applications for the research within each domain, many of which can affect public policy. For example, research on divided attention using driving simulators has suggested that talking on cell phones significantly reduces driver’s braking time, leading to greater risk on the road. Research on memory has suggested that, in educational settings, what students “feel” is the best and worst way for them to learn is often the opposite of what actually leads to the best learning. Research on language has suggested that phonics may indeed be the best method of teaching schoolchildren to read.

Self-identification

Science

Because it relies on the scientific method, cognitive psychology has always self-identified as a science. One common misconception regarding psychology is that it is either not a science at all or a “soft science” when compared to more traditional disciplines like chemistry or physics. Cognitive psychologists argue that it is in fact a “hard science,” as it not only involves experimentation and hypothesis testing, but it also involves mathematical modeling of cognitive processes as well.

Characteristics

Cognitive psychology can be distinguished from other fields of psychology (such as industrial/organization psychology, social psychology, clinical psychology, or counseling psychology) by its subject matter (i.e., the internal workings of the mind) and its methodology (i.e., the *scientific method*) together. Specifically, cognitive psychology is the only area of psychology that focuses on the scientific study of the mind. It can also be differentiated from some areas of psychology by its emphasis on experimental methodology (as opposed to survey research, for instance).

A closely related field is ► [cognitive neuroscience](#). Cognitive psychology differs from *cognitive neuroscience* in that it focuses more on how cognitive processes work than on their neural underpinnings. Take, for example, the mental rotation study described above. There, the researchers examined a question regarding how a process worked without concern for the neural source of the process. Still, many cognitive psychologists are also cognitive neuroscientists, and most cognitive psychology textbooks include at least some cognitive neuroscience and reference to neural underpinnings.

Relevance to Science and Religion

Though cognitive psychology’s subject matter – the mind – might seem somewhat relevant to

religion insofar as many religions have notions about “mind,” cognitive psychology has largely left debates about the source of the mind to philosophers of mind. Whereas philosophers debate about such issues as whether reductive physicalism, non-reductive physicalism, or other approaches are better conceptualizations of the mind cognitive psychologists instead focus on testable hypotheses about specific cognitive processes, theories that are falsifiable, and empirical data generated through experimentation. The interest is more in discovering *how* specific mental processes work than in determining their source. While most cognitive psychologists tend to assume that mental processes are the result of neurological processes, it is entirely possible for a cognitive psychologist to be agnostic regarding the source of mental processes. Take the factory example or the mental rotation study described in response to section “[Description](#)”: In both cases, one can theorize about how a process works and can design experiments to test hypotheses about how that process works, all without speculating on the origin of the process or where exactly it is taking place (i.e., who is working in the factory, whether it is people or robots on the assembly lines, or in which particular room a given process takes place).

Outside of mainstream cognitive psychology, there is a growing domain of research examining the nature of religious beliefs and subjective reports of religious experiences. This relatively new area has its roots in social psychology and greatly overlaps with evolutionary psychology. As with evolutionary psychology, cognitive psychology does not focus on the religious validity of an individual’s belief or experience (as in the philosophy of religion) but, rather, is interested in exploring the nature of the beliefs and experiences themselves as well as in individual differences in such beliefs and experiences.

Sources of Authority

As a science, cognitive psychology has its roots in the dialectic process described by George Hegel (Sternberg [1999](#)), whereby the route to

discovering truth is assumed to start with a thesis, followed by an antithesis to that idea. Eventually, a synthesis that maintains only the best elements of both emerges. The idea is that, through the constant challenge of existing ideas, ideas are continually modified or replaced in ways that take a field one step closer to the truth. The logic is not unlike that behind US court systems or US governmental processes; in all of these cases, from the pitting of opposing forces against one another comes a better approximation of the truth than from one side alone. This is the logic used in cognitive psychology. Cognitive psychology as a field does not make appeals to authority alone for obtaining information. Within cognitive psychology, ideas must stand the test of scrutiny over time. In principle, all ideas are subject to scrutiny, even those of established researchers who are considered experts. Therefore, while there are top-tier journals and widely respected researchers and widely respected institutional programs, appeals are not to authority alone. One must make a case for any claim using logic in conjunction with empirical data, and once a case is made, it is subject to critical evaluation by peers within the field. This scrutiny happens both in the peer-review process and in the fact that published material is immediately scrutinized by other scientists.

For accurate information on the current state of the field for novices, introductory and advanced (Sternberg 1999) cognitive psychology textbooks are usually good sources. These sources usually provide some historical context as well as a lot of the now-classic studies in the field. For those with more experience in the field, journals such as *Trends in Cognitive Sciences*, *Current Directions in Psychological Science*, *Psychological Science*, *Psychonomic Bulletin & Review*, *Cognitive Psychology*, *Journal of Experimental Psychology: Learning, Memory & Cognition*, *Journal of Experimental Psychology: Human Perception & Performance*, *Journal of Memory and Language*, and *Memory & Cognition* are great sources of the latest research in cognitive psychology. Other top journals that frequently include cognitive psychology articles are *Journal of Experimental Psychology: General*,

Psychological Bulletin, and *Psychological Review*. What all of these sources (textbooks and peer-reviewed journals) have in common is that they contain contributions written by experts in the field.

Ethical Principles

The ethical principles that guide this discipline are the same as in other areas of science (i.e., honesty and integrity in conducting research and reporting results), with the addition of ethical guidelines aimed at protecting the human participants on which research in cognitive psychology depends. The American Psychological Association currently lists five general principles that all psychologists, including cognitive psychologists, are expected to follow in their research. The first principle concerns beneficence and non-maleficence, which is an obligation to strive for providing benefits from research and minimizing harm as a result of it. The second principle involves fidelity and responsibility. This is an obligation to uphold professional and ethical behavior at all times, which includes taking responsibility for one's actions and minimizing conflicts of interest. The third principle involves integrity, which is an obligation to conduct research in an open, careful, and honest manner in search of scientific truth. The fourth principle involves justice. One aspect of justice in psychology involves seeking to distribute research benefits fairly to all. The second aspect of justice involves the responsibility of knowing the limits of one's own knowledge in the hopes of minimizing abuses of power that may result from overstating such knowledge. The final ethical principle involved in psychology involves respect for people's rights and dignity. This includes being sensitive of the needs of special populations.

Cognitive psychologists working within academic institutions are generally required to follow guidelines set by an institutional review board (IRB) and to have all research proposals approved by this board before collecting data. Cognitive researchers who use animal models

are bound by additional ethical guidelines for the humane treatment of animals.

Key Values

The key values of cognitive psychology include critical thinking and critical evaluation of ideas, honesty, integrity, logical coherence of ideas, tightly controlled and well-designed experiments, and replication of experimental findings.

Conceptualization

Nature/World

In line with other areas of science, nature and the world can be viewed as operating according to the laws of physics, with humans and other biological organisms having come to be through evolution.

Human Being

Cognitive psychology's view of the concept of "human being" is generally the same as that taken in evolutionary psychology: A human being is the subspecies of *Homo sapiens* known as *Homo sapiens sapiens*.

Life and Death

Cognitive psychology as a field does not really concern itself with issues of the origins of life or of the matter of death. Perhaps only to the extent that evolutionary psychology is relevant to cognitive psychology (as in the proposed adaptiveness of certain cognitive processes) is the notion of death relevant.

Reality

There are two ways in which the notion of reality is relevant to cognitive psychology. First, George Hegel's dialectic approach is relevant here, as the idea that reality can come to be understood through a process of continually pitting of opposing ideas against each other is prevalent in cognitive psychology. Second, a relevant distinction

is between objective and subjective reality, as cognitive psychology relies on objective methods of investigation, yet often studies aspects of people's subjective realities using these objective methods. For example, whether people can form visual images in their minds when thinking is a question about a person's subjective reality that is examined using objective means (such as by measuring reaction time in different experimental conditions, as in the mental rotation study described in response to section "[Description](#)" above).

What has research in cognitive psychology suggested about subjective reality? One overarching finding is that past experiences affect the way that reality is experienced by a person. Existing knowledge affects the way that incoming information is perceived, as shown by the effects of context on perception, such as in the tendency to think that one hears a sound that is actually missing but would be predicted by the surrounding context (as when a phoneme is spliced from a word and replaced with a cough). Existing knowledge also influences what external information a person will attend to, as shown by findings indicating a bias to detect items in a scene that are personally or contextually relevant. Existing knowledge also affects how experiences are remembered, as shown by findings suggesting that people remember passages about famous people differently than identical passages about non-famous people (existing knowledge about the famous people gets incorporated into the memories for what the passages about them said). Finally, existing knowledge also affects decision-making and reasoning as shown by the many documented ► [biases and heuristics](#) that people use, such as the "*confirmation bias*" and the "*availability heuristic*."

Knowledge

There are two ways of viewing knowledge that are relevant to cognitive psychology: First, human knowledge is itself subject matter for study in cognitive psychology; second, as in any field, knowledge is relevant to becoming an expert at cognitive psychology.

Knowledge as a Subject of Investigation. With regard to the investigation of knowledge itself, a review of theories of knowledge representation and acquisition would go beyond the scope of this chapter. There are many theories of knowledge representation and knowledge acquisition in cognitive psychology. These are continually going through the dialectic process, without any clear sole winners as far as how knowledge is represented and acquired. Many good candidate theories exist, and scientists continue to investigate these. That said, a person's knowledge is thought to reflect the external world that he or she has experienced. As such, knowledge can be correct or incorrect in terms of truthfulness; stereotype representations are a good example. Particular word representations in the knowledge base reflect exposure to that language over time, as do other representations relevant to language (such as the syntactic aspects of language). Also, particular associations in memory (such as between bread and butter or between thunder and lightning) reflect exposure to the repeated cooccurrence of these things over time.

Knowledge as Expertise in a Field. With regard to the second conception of knowledge – knowledge as it applies to becoming an expert in the field of cognitive psychology – a cognitive psychologist must have a good grasp of the principles of experimental design and data analysis and of current theory and theoretical issues. Much research in cognitive psychology is domain-specific; therefore, researchers generally become experts in a particular domain of cognitive psychology (such as memory or language or attention). Becoming an expert requires knowledge of the literature and the history within the domain as well as knowledge of the current issues and controversies within the domain.

Truth

As mentioned in response to section “[Sources of Authority](#)”, George Hegel's notion of the dialectic process is perhaps most relevant to cognitive psychology's quest for truth about the nature of cognitive processes. A culture of open skepticism

is necessary in order to make progress toward discovering the truth.

Perception

Like knowledge, cognitive psychology considers perception itself a domain of research. Perception is not the external stimulus itself but, rather, the experience of the observer in response to that stimulus. Perception is understood to be complex, involving both bottom-up processes (i.e., sensory information coming into the system) and top-down processes (i.e., existing knowledge and memories exerting a role). Top-down effects are shown by the fact that the context in which a stimulus is presented affects how it is perceived. For example, when the first phoneme is spliced from a recording of a person speaking a word that ends in the sound *eel, participants will tend to perceive the sound “meal” if it is placed within the context “The *eel was on the table.” They will tend to perceive the sound “heel” if it is placed within the context “The *eel was on the shoe,” and they will tend to perceive “peel” if it is placed within the context of “The *eel was on the orange.”

Because knowledge itself (as well as the particular subset of knowledge that is most active at any given moment) will vary from person to person, it follows that perception in any given situation could vary from person to person as well. For example, if people are played the song “Another One Bites the Dust” in reverse, they are more likely to claim to hear the words “I like to smoke marijuana” when told beforehand that the reverse piece might contain references to marijuana than when told nothing beforehand. What is perceived from the reversed music is related to the knowledge that has been activated beforehand.

Time

Time is relevant to cognitive psychology in two ways: (1) Time is an important measurement tool in cognitive psychology, and (2) the subjective perception of time and the seemingly uniquely human ability to escape from the present moment are topics of interest to cognitive psychologists.

A basic tenet of cognitive psychology is that mental events take time. Therefore, one of the ways in which mental processes are studied objectively is by examining their time course, or how quickly they can be carried out. Measuring reaction time across different experimental conditions is therefore a common method in cognitive psychology. This was the method used in the mental rotation study described in response to section “[Description](#)”, where it was shown that reaction time to indicate that two shapes were identical increased linearly as the degree to which the second shape was rotated from the position of the first increased. Another common method in cognitive psychology that involves time is the response-signal (or signal-lag) procedure. In this method, the researcher varies the amount of time that a participant has to make a response to a stimulus. On some trials, there is more time allowed; on others, there is less. The goal is usually to determine when in time a process begins to emerge. For example, if some of the trials in question were items that were seen earlier in the experiment (“old” items) while others were new items, above-chance old-new discrimination might not begin to emerge until 300 ms or so. That is, on trials where fewer than 300 ms are given to make a response, old-new discrimination is at chance-performance levels. At time lags beyond approximately 300 ms, significant old-new discrimination can be seen, suggesting that the process requires approximately 300 ms to occur. Some processes require less time poststimulus to occur; others require more time.

Also related to time in cognitive psychology is people’s subjective experience of time. Relevant here are the notions of mental time travel and the subjective perception of time. Some argue that one unique feature of humans is their ability to mentally travel through time, a term that Endel Tulving termed *chronesthesia*. Humans can both think about the past and anticipate the future; memory plays a major role in this ability. Somewhat related to the notion of mental time travel is the notion of subjective time perception. Research suggests that human subjective perceptions of time can be relative; that is, they do not

necessarily follow objective indices of time. For example, one recent study showed that wearing prism glasses that distorted visual spatial perception appeared to distort time perception as well, suggesting that space and time representations are intimately tied in the mind. As another example, a different study showed that perceptions of time varied as a function of expertise in a relevant domain, with domain experts perceiving slower durations of domain-relevant stimuli than domain novices. This suggests that existing knowledge not only affects perception of visual and auditory stimuli (as described in response above under “perception” and “reality”), but it also affects perceptions of time (or perceptions of the duration of an occurrence).

Consciousness

At the broadest level, though many cognitive psychologists might argue that consciousness is an emergent property of activity occurring in the brain, many leave the specifics of debating about the source of consciousness to philosophers of mind. Still, many cognitive psychologists discuss the nature of consciousness, and a review of these discussions would go beyond the scope of this chapter.

In cognitive psychology, consciousness typically refers to the extent to which an individual is aware of a stimulus or mental process and the extent to which a mental process is under an individual’s self-control. For instance, cognitive psychologists often make the distinction between conscious, controlled processes, and automatic processes. An automatic process is one that happens very quickly in response to a stimulus. Its mechanisms tend to circumvent one’s own awareness and intentional control, perhaps because it happens too quickly. One is generally aware of the outcome of an automatic process but not the process itself that produced that outcome. An example is letter perception. Once a letter appears on a screen, it is automatically perceived by a person fluent in that written language. It happens rapidly and seemingly “just happens,” as the person cannot explain *how* it happens. The process itself is not open to introspection in that way. The process is also not under the person’s

willful control, as the person cannot stop the process for letter perception once the stimulus has initiated it: It comes to completion automatically; the person perceives the letter. In contrast, a conscious, controlled process is slower (e.g., requires more time to be carried to completion) and tends to occur within a person's span of awareness. It also tends to be under the person's intentional control, meaning that the process is not automatically carried to completion once initiated by a stimulus, but can be stopped willfully. An example is attempting to recall an episode from earlier in the week in response to a question. This takes more time than perceiving a letter on the screen, and a person can generally introspect on what he or she is doing during the attempt at recalling; furthermore, the person can stop the act of attempting to recall at any point in the process.

Consciousness in cognitive psychology can also refer to the idea that one's thought and behavior can be influenced by stimuli or memories that occur outside of his or her own awareness. For example, the phenomenon known as implicit memory is the finding that people can exhibit memory for information when tested indirectly, even when they appear to show no explicit memory when memory is tested directly. For example, even when a person fails to recall the word "POLICE" from an earlier study list, he or she will show an increased probability of responding to the word stem POL____ with the word "POLICE" relative to if the word "POLICE" had not appeared in the earlier list. This suggests that a memory for a prior episode can be present in one's mind and able to exert an influence on his or her thought and behavior, even though the person cannot consciously bring to mind the memory itself, or in this case, the reason why the word popped into mind.

A related issue is the controversial issue of subliminal perception, which is the idea that stimuli that are presented below the threshold of conscious awareness (such as stimuli that are masked and presented too rapidly to be identified) can still affect people's behavior even though they were unaware of the occurrence of these stimuli.

The issue of subliminal perception, however, is controversial.

Rationality/Reason

Rationality and reason are also themselves a topic of study within cognitive psychology. Two domains in particular are relevant to rationality and reason: (1) executive function and (2) decision-making.

Executive Function. Related to the notion of rationality and reason, executive function is the term used to describe the set of processes involved in controlling other cognitive processes. For example, in order to perform many high-level tasks, one must selectively attend to certain pieces of information while preventing irrelevant pieces of information from coming to mind. To do so, one may need to activate certain processes while suppressing others. Much evidence points toward a correlation between executive function and general fluid intelligence, which is the ability to problem solve or think creatively. In addition, evidence from *cognitive neuroscience* suggests a role of the prefrontal cortex in executive function.

Decision-Making. While many studies in the area of decision-making have focused on irrational behavior (i.e., findings suggesting that humans often ignore basic statistical rules, instead relying on heuristics or biases), there has been a recent interest in examining cases where people behave rationally. For example, people can sometimes override their emotions in favor of a rational response. For instance, susceptibility to framing effects has been shown to involve the amygdala (responsible for emotion), while the ability to resist framing effects has been shown to involve the frontal lobes. Interestingly, just as research in *cognitive neuroscience* has shown a relationship between frontal lobe function and executive function, this research suggests a role of the frontal lobes in making rational decisions.

Mystery

Mystery is not a term that is generally used in cognitive psychology. There are topics that are not yet well understood, but because the field concerns itself with ideas that can be empirically

tested, the focus tends to be on testable hypotheses. Thus, rather than calling something a mystery and leaving it at that, a cognitive psychologist will develop a hypothesis and aim to test it in the lab. If an idea is not something that can be investigated scientifically, it is generally not considered relevant to cognitive psychology.

Relevant Themes

Though the investigation of religious experience has largely remained outside the realm of mainstream cognitive psychology, its related field of cognitive neuroscience has begun to see some exploration of the neural substrates of subjective religious experiences. For example, some have induced subjective religious experiences in the laboratory by applying strong magnetic fields to certain parts of the brain using ► [transcranial magnetic stimulation \(TMS\)](#). Others have noted a link between specific brain activity (in the temporal lobe) and subjective religious experience based on data from individuals with a specific type of epilepsy. Importantly, however, such studies do not actually cross over from being science to being religion, as they merely examine subjective states of awareness without addressing the religious validity of the experiences. In other words, regardless of any particular research finding regarding religious experiences, it will remain possible for one to remain completely agnostic regarding whether that religious experience involves divine inspiration or is simply the result of a particular neural state that produces a feeling that is labeled a religious experience (in the same way that a particular neural state might produce a feeling that is labeled a tip-of-the-tongue state). No research finding on religious states will ever prove or disprove those religious tenets that require faith. Thus, it will remain possible for one who is faithful to remain faithful in the face of research findings on the neural substrates of religious experience. It will also remain possible for the nonbeliever to continue to assume no need for a belief in the supernatural. In this way, scientific research on subjective religious experience will always remain separable

from religion itself, even though the topic of researching subjective religious experience may seem tangentially related to religion itself.

Cognitive Science

Gregory Peterson

Department of Philosophy and Religion, South Dakota State University, Brookings, SD, USA

A term used to refer to those disciplines involved in the study of mind and thought, usually understood to include the fields of cognitive psychology, cognitive neuroscience, psycholinguistics, branches of artificial intelligence, cognitive ethology (also referred to as animal psychology), and philosophy of mind. Related fields include anthropology, evolutionary biology, primatology, and behavioral economics. The roots of cognitive science are generally understood to coincide with the maturing of theories of computation and the development of digital computers in the 1940s and 1950s.

Description

Cognitive Science of Religion (CSR) is a field that attempts to explain causally the recurrence of religious beliefs and practices, and the role they play in social and political arrangements by appealing to the underlying mental structures and dynamics that make people generally receptive to certain ideas and actions. CSR lies at the intersection of the cognitive sciences (especially cognitive, developmental, and evolutionary psychology), religious studies, and anthropology.

Though the field is very young, cognitive scientific approaches to the study of religion find their roots in the 1970s. Dissatisfied with a perceived paucity of crossculturally useful *causal* theories of religious phenomena, and drawing inspiration from Chomskian linguistics, early researchers in the area such as E. Thomas Lawson and Robert McCauley began considering whether ordinary human cognition provides something analogous to a “universal grammar” of religious ritual. In parallel, advances in schema theory from cognitive psychology and the role schemata play in shaping perception informed Stewart Guthrie’s decidedly cognitive resuscitation of the “anthropomorphism” theory of religion. In the 1980s, breakthroughs from developmental psychology concerning the early-developing (and apparently pre-cultural) mental structures in babies were appropriated by Dan Sperber in continuing to develop a cognitive scientific approach to cultural phenomena

generally. These conceptual and empirical developments led to several important books published in the early 1990s using a cognitive approach to the study of religion, specifically by Lawson and McCauley (1990), Guthrie (1993), Pascal Boyer (1994), and Harvey Whitehouse (1995). Experimental and other empirical testing of theories in the area and attempts to connect isolated projects began in the 1990s, birthing the subfield. These cognitive approaches came to be known as Cognitive Science of Religion in 2000 (Barrett 2000) because of a review article in *Trends in Cognitive Sciences* by Justin Barrett.

Self-identification

CSR self-identifies as a science but still relies heavily upon insights from humanities disciplines such as philosophy and religious studies. CSR justifies its identification as a science by the fact that it employs standard scientific assumptions and methodological frameworks. Cognitive scientists of religion attempt to generate empirically falsifiable hypotheses that may be tested through experimentation or other controlled forms of investigation including survey, interview, and semantic analyses of texts. Sources of data must be objectively observable, e.g., participation in religious rites, individual reaction times to computer-presented displays, answers on questionnaires, and verbal responses. Cognitive scientists of religion adopt a methodological naturalism perspective, seeking strictly natural mechanisms for the phenomena under considerations, foregoing alleged supernatural causes. As with other areas of cognitive science, not all cognitive scientists of religion are scientists or conduct scientific research.

Characteristics

CSR is related to and overlaps with Psychology of Religion, but the two fields have different emphases. Psychology of Religion, like other areas in psychology, tends to take individual thought and behavior as the primary unit of

analysis. In contrast, CSR attempts to explain general patterns across individuals. For instance, a psychologist of religion may be interested in why a given individual is an enthusiastic theist, whereas cognitive scientists of religion are more concerned with why theism is generally prevalent across cultures. Compared with *Psychology of Religion*, CSR places a greater emphasis on explaining why people (generally) are religious and why types of religious belief and practice are crossculturally recurrent, and shows little concern for the psychological consequences of religion.

CSR is sometimes conflated with another neighboring area, evolutionary studies of religion. While CSR draws heavily upon insights from evolutionary psychology and behavioral ecology, studies in CSR need not be evolutionary (and evolutionary studies are frequently not cognitive). Cognitive explanations of religious phenomena, which characterize CSR, appeal to mental structures and processes as informing or constraining the range of ideas or actions likely to be recurrent in a population. Evolutionary accounts may complement these cognitive ones by providing explanations for why the particular mental structures have arisen as they have.

For a recent discussion of CSR's distinctive features, see Barrett (2007).

Relevance to Science and Religion

CSR is directly and decidedly a science and religion area. It uses scientific methods to study the causes for religious belief and practice. An area of dispute is what bearing naturalistic explanations of religion from CSR have upon justification and warrant of religious beliefs.

Sources of Authority

Cognitive scientists of religion generally view their scholarship as gradually and collectively accumulating knowledge through controlled empirical investigation supplemented by

theoretical analysis. Consequently, as in the natural sciences, the most valued authoritative sources in this discipline are recent refereed journal articles rather than classic texts or pronouncements of prestigious individuals. The most important journal in the field is the *Journal of Cognition and Culture*. Nevertheless, as compared with neighboring sciences (such as cognitive psychology), books by field leaders carry greater weight, and well-developed theoretical constructs have been widely appropriated before refereed articles offering empirical evidence in their support have appeared.

Ethical Principles

In general, CSR scholarship is governed by standard scholarly ethical principles requiring honesty in reporting and not claiming credit for another's work. Observational data from human subjects are to be collected either through public observation or, if not in public, with the consent of those being observed. The gathering of data through interviewing or other forms of nonobservational interaction with participants is regulated in the same way as all psychological research.

Key Values

As a field scientifically studying religion, CSR values even-handed neutrality when treating various worldviews. While this ideal is difficult to live up to, CSR scholars are quick to call each other out for practicing stealth theology, anti-theology, or favoring certain religions over others. Cognitive scientists of religion have inherited a skeptical stance toward commonsense assumptions from their psychologist colleagues.

Conceptualization

Nature/World

In CSR, *nature* (as in "human nature") typically refers to those features of human thought and

behavior that are cross-culturally recurrent and do not tend to depend heavily upon any specific environmental conditions – be they physical, ecological, or social. Language use, walking, and regarding other humans as having minds are all seen as paradigmatically natural human practices, part of human nature. This broad sense of “nature” accepts environmental conditions as inextricable factors contributing to human thought and behavior and includes environmental regularities as part of the natural condition for humans.

Another sense of “nature” or “natural” used in CSR concerns the fluency or automaticity of thought or behavior. Those capacities that require little conscious effort or deliberation are said to be more natural than those that require more effort. With much practice, other processing fluency may occur as in many forms of expertise. For experts, a specific kind of information processing may become “natural.”

Both senses of what is part of human nature and what is natural can be used in a relative manner. That is, different attributes, ideas, or practices may be said to be more or less natural. Language use is more natural (in both senses) than algebra. Religious thought, according to CSR, is more natural in the first sense (and for most people in the second sense as well) than scientific reasoning. That something is judged to be part of human nature or not or relatively natural does not constitute a value judgment.

The concept *world* does not feature prominently in CSR, but could indicate the external environment of humans (as in “the world in which Tibetan monks live”) or the general entirety of humanity (as in “religion is practiced around the world”).

Human Being

In CSR, human beings are to be studied as members of a particular species, *Homo sapiens*. How human beings compare with other animals in terms of cognitive capacities and ability to develop cumulative culture (as in religious traditions) is an area of contention.

Life and Death

Cognitive scientists of religion are not concerned with the origins of life generally, but do consider folk conceptions of life, death, and the afterlife.

Reality, Knowledge, Truth, Perception

These four concepts are interrelated in CSR. CSR generally adopts the view that there is a real world that human cognitive systems normally perceive and understand reliably. For the sake of processing efficiency or utility, human conceptual systems may, however, lead to errors in accurately discerning reality. Scientific methods and reason are seen as methods for overcoming this inaccuracy and discerning truth about the world. Perception is the principal process through which humans come to know reality through the senses. Knowledge amounts to accurate beliefs about the world.

Time

The concept of historical time is not important in CSR. Cognitive faculties are assumed not to have changed meaningfully through history. When considering origins of religious thought, however, considerations of prehistory and evolutionary pressures in ancestral conditions lead to a longer-scale view of time.

Consciousness

CSR has not been concerned with philosophical questions concerning consciousness. Cognitive scientists of religion tend to use fairly common-sense understanding of consciousness, often labeling “conscious” only those processes of which one has either awareness or which one can verbalize. Nonconscious cognitive processes are seen as a major source of information and constraint on the emergence of recurrent ideas or cultural practices.

Rationality/Reason

As in psychology, CSR focuses on how people think and reason rather than whether they are rational or the nature of rationality. Reason is viewed as a consciously accessible, reflective

cognitive activity that is less tightly constrained than nonconscious thought.

Mystery

Cognitive science of religion resists classifying phenomena as mystery. Instead, it attempts to dissect mysteries into empirically tractable problems.

Relevant Themes

Recurrence

Cognitive scientists of religion often write about the recurrence of cognitive capacities and of ideas, behaviors, and forms of cultural expression. Recurrence refers to appearance across individuals. A recurrent cognitive capacity is fluency in processing human faces. Religion is said to be a recurrent form of cultural expression in that it appears across individuals and cultural groups but is not, strictly speaking, universal. CSR aims to account for recurrence of religious phenomena by appeal to recurrent cognitive capacities.

Description

Cognitive science is an interdisciplinary science of the mind – particularly, but not exclusively, the human mind. One major disciplinary contributor is psychology. The subfields of psychology that contribute most to cognitive science are cognitive psychology, cognitive developmental psychology, evolutionary psychology, social cognition, and psycholinguistics. Cognitive psychology, a designation attributable to Ulric Neisser’s 1967 book of that title, is concerned with the structures and dynamics of (human) information-processing systems including attention, concepts and categorization, language structure and use, memory, thinking and reasoning, and sensation and perception (Neisser 1967). (Cognitive psychology should be distinguished from therapeutic forms of psychological study and practice that include the label “cognitive,” particularly cognitive therapy and cognitive-behavioral therapy.) Rather than having a different content focus, cognitive developmental psychology concerns how these mental structures and dynamics are acquired and if and how they change over the course of the life span. Particular attention has focused on early childhood and how children come to understand the world around them and learn to act upon it. Similarly, evolutionary psychology brings a particular perspective to the study of cognition rather than primarily representing a content area. As applied

to the study of cognition, evolutionary psychology attempts to explain why certain mental structures might have evolved to solve information-processing problems as opposed to others and how the cognitive architecture of *Homo sapiens sapiens* might differ from that of ancestral hominids and other animals and why (Buss 2007). Psychologists taking an evolutionary perspective will sometimes study the minds and behaviors of nonhuman species. Social cognition is a focus of social psychology on social thought, how humans form and use social categories (such as roles, races, groups, and relations), and how different cognitive capacities are activated by and, in turn, shape social interaction. On the one hand, psycholinguistics is the subfield of psychology concerned with how cognitive architecture enables the acquisition and use of language and how the language faculty then helps explain the range of linguistic expression observed around the world (Chomsky 1968). On the other hand, psycholinguistics concerns how language use impacts other cognitive capacities such as concept formation, reasoning, creativity, and perception. Because of its focus on one particular cognitive capacity that gives rise to a particular form of cultural expression, psycholinguistics is often treated as a distinct discipline rather than a subfield of psychology.

The genesis of the contemporary cognitive emphases in psychology may be traced to the so-called cognitive revolution that started in the late 1940s and gathered momentum in the 1950s and 1960s. For approximately the first half of the twentieth century, scientific psychology was dominated by behaviorism, a school of thought championed by John B. Watson and B. F. Skinner, wherein the only legitimate psychological science was the study of human behavior as it was shaped by environmental contingencies. Mental states were considered irrelevant and thus entirely ignored. This behaviorist focus assumed that within the range of normal biological development, the only factors that affected human behavior and led to differences in dispositions, expression, and so forth were environmental. The cognitive revolution rejected both the idea that minds and mental states could not be studied scientifically and the radical empiricist assumption

that human minds are naturally formless, blank slates indiscriminately waiting for the environment to write anything upon them. Early experiments demonstrated that people and animals are biased to create some associations over others (such as fear of snakes as opposed to daisies) and that human working memory (what can be held in conscious attention at once) is limited to approximately seven (plus or minus two) chunks of information. These experiments demonstrate that it is possible to examine the architecture of the human mind and how it might be naturally biased or restricted in the way it processes information. The findings also suggest that in the background of interindividual and intergroup differences in thought and behavior might be species-wide psychological generalities.

The broadening of psychology by the cognitive revolution has enabled psychology to explore fruitfully many areas of human thought and behavior. Exciting topics beginning to receive considerable attention over recent decades include creativity, moral and normative reasoning, social intelligence and related areas such as perspective taking and empathy, and applications to nonlinguistic forms of cultural expression such as art and aesthetics, music, and religion. Essentially, any area of thought is now considered amenable to psychological investigation.

Self-identification

Psychology self-identifies as a science and often self-consciously so. Because of the cultural prominence of the therapeutic side of psychology, psychologists active in the scientific side of the field sometimes refer to their work as “psychological science” or, if appropriate, “cognitive science.” This scientific face of psychology justifies its identification as a science by the fact that it employs standard scientific assumptions and methodological frameworks. Psychologists attempt to generate empirically falsifiable hypotheses that may be tested through experimentation or other controlled forms of investigation. Sources of data must be objectively observable behaviors such as reaction times to

computer-presented displays, answers on questionnaires, eye gaze direction, verbal reactions, pulse rate, or blood flow to parts of the brain. These data enable inferences to mental states, structures, and dynamics. Though psychologists may use qualitative data to contextualize and amplify their studies, studies based on quantitative data are the gold standard.

Like all natural sciences, psychology relies heavily upon experimental methods, but because ethical and practical constraints limit the amount of experimental control that psychologists can exercise over their subjects (particularly human subjects, also called “participants”), psychologists use statistics to control for those factors they cannot manipulate. For instance, when studying memory for lists of words, a psychologist could experimentally manipulate whether the words are presented orally or visually, but only statistically control for the age, sex/gender, or nationality of the subjects.

Behind all of these scientific methods, psychology presumes methodological naturalism. That is, psychologists generally search out strictly natural mechanisms for the phenomena under considerations, foregoing alleged supernatural causes, even in the case of psychology of religion.

Characteristics

Psychology is further distinctive among the so-called social sciences in that it generally takes a single individual as its unit of analysis. Ultimately, psychologists are interested in explaining individual thought, beliefs, and behavior; groups, such as those based on age, gender, nationality, etc., are only relevant insofar as placing individuals into them can help explain variability. Consequently, psychologists often take the perspective known as methodological individualism, which implies that the origin and development of social institutions can – and should – be explained in terms of the summation of the actions of individuals.

Psychology is generally distinguished from the other contributors to cognitive science by its reliance on data gathered from the behavioral

activities of individuals (usually humans). Further, unlike conventional anthropology, linguistics, philosophy, and much computer science, psychology places heavy emphasis on what can be learned through experimental methods, as described above.

Like other contributors to cognitive science, however, psychologists see the mind as a computer – that is, as a machine that is capable of processing information. The principles of computation that go into creating computers are therefore used to understand how the mind works.

Relevance to Science and Religion

From its inception, modern psychology has contributed to the scientific study of religion. Psychologists have investigated religious experience, origins of religious beliefs and practices, formation of individuals’ god images, religious development and conversion, and how religiosity impacts social attitudes, morality, and psychological adjustment – to name just a few representative areas. Questions such as whether religious participation is good or bad for individuals, whether religion is the result of psychopathology, and what emotional or relational functions religions serve are all decidedly psychological questions. This subfield of psychology called psychology of religion can claim more than 100 years of history, though its decidedly cognitive expression, such as that manifested in the area called cognitive science of religion, did not begin to emerge until the end of the twentieth century (Lawson and McCauley 1990; Barrett 2004).

Sources of Authority

As with scientists generally, psychologists view their scholarship as gradually and collectively accumulating knowledge through controlled empirical investigation supplemented by theoretical analysis. Consequently, the most valued authoritative sources in this discipline are recent refereed journal articles rather than classic texts or pronouncements of prestigious individuals.

Journal articles receive their authority by the assumption that they have been carefully scrutinized for methodological rigor and theoretical importance by experts in the field who are often blind to the identity of the authors and their institutional affiliation. The ideal empirical journal article in the field is written in such a way that critical readers could replicate the protocol and analyses for themselves. The truth of psychological claims is meant to be based upon broadly accepted principles of accurate scientific investigation and sound statistical reasoning and logic. Scientific psychologists are suspicious of arguments from authority, of the use of anecdotes as evidence, and of rhetorical flourish. Partly to reduce the influence of the latter on the way arguments are perceived, most psychological journals require that all submissions conform to the stylistic principles dictated by the American Psychological Association (i.e., APA style) (American Psychological Association 2009).

Ethical Principles

Today, psychologists have to comply with ethical guidelines provided by professional associations or university-wide boards (e.g., the Institutional Review Board system in the USA) that restrict the kinds of studies that are permitted on the basis of whether participation is likely to involve any ill consequences and ensure that participants' responses are anonymous and confidential, unless the research question requires otherwise. Most professional journals in psychology require that any data presented be obtained in accordance to ethical guidelines. Many psychological studies, however, use deception or misinformation in order to obtain data that would otherwise be impossible to gather. In all studies, but particularly in those that involve deceptions, participants are thoroughly debriefed after participation.

Key Values

Among the fundamental values to which most psychologists subscribe is a *healthy skepticism*

that leads to *questioning assumptions*. This skepticism motivates the investigation of issues that would otherwise be taken for granted. For example, most people believe that parental influence is the strongest determinant of children's religious or political orientation, that playing violent video games causes adolescents to become more violent, and that their preference for one object or face over another is not influenced by familiarity, but, in most cases, these beliefs are not based on data. Psychologists see it as their objective to provide such data, whether it confirms or disconfirms the commonly held belief.

In addition to this questioning approach, psychologists aim to avoid injecting their prejudices into the scientific process. It is good psychological practice to test an explanation that one believes to be correct against other, alternative explanations, even when the original explanation appears adequate to account for the phenomenon at hand.

Conceptualization

Nature/World

In psychology, *nature* can have several meanings. As psychologists explore human thought and behavior, they often consider whether mental structures, behavioral patterns, or even neural architecture are best understood as a consequence of *nurture* – the contingent factors in a given human's environment – or *nature*. *Nature*, in this context, typically refers to human biological endowment including genetics. Contemporary psychologists know full well that the theoretical constructs of nature and nurture are never disentangled in the real world. Even solidly biological drives, such as for food, that might appear paradigmatic cases of natural features of humans are impacted by environmental (nurture) factors from biochemical environments in which human bodies develop and function to the variable environmental conditions that channel these drives into specific behaviors.

Nature (as in “human nature”) may also refer to those features of human thought and behavior

that are cross-culturally recurrent and do not tend to depend heavily upon any specific environmental conditions – physical, ecological, or social. For instance, upright, bipedal walking is a human universal (barring developmental disorders or environmental insults) that is not dependent upon special environmental or social conditions. As such, walking is part of human nature and might be termed “natural.” Similarly, though spoken languages vary across cultures, the ability to use spoken language is cross-culturally recurrent, appearing to only require general human biological endowment plus ordinary human environmental conditions. Thus, spoken language, too, is part of human nature. This broader sense of “nature” accepts environmental conditions as inextricable factors contributing to human thought and behavior and includes environmental regularities as part of the natural condition for humans.

A third sense of “nature” or “natural” used in psychology concerns the fluency of information processing or automaticity of behavior. Those capacities for thought and behavior that require little conscious effort or deliberation are said to be more natural than those that require more effort. To illustrate, from birth, people readily and automatically discriminate human faces in their environments and (barring developmental disorders or environmental insults) continue to show fine-grained facial discrimination throughout life. The ease with which humans process information about human faces is evidence of its relative naturalness. With much practice, other processing fluency may occur as in many forms of expertise. Chess masters, for instance, can automatically process relative positions of chess pieces much faster and easier than novices. For these experts, this specific kind of information processing has become “natural.”

The concept *world* does not feature prominently in psychology. “The world” could refer to the entire human population as when saying that a highly recurrent human trait is common “everywhere in the world.” “The world” could also be used to indicate the external environment of humans as when psychologists talk about how people try to understand the world they live in.

In this context, “the world” can be synonymous with *nurture* and antonymous of *nature*.

Human Being

For the psychological scientist, human beings are to be studied as natural objects, members of a particular species. Thus, the psychological study of humans and that of animals (which often falls under the scope of cognitive ethology or behavioral ecology) are assumed to require the same methodological tools. How human beings differ from other animals is an ongoing area of contention with some psychologists emphasizing what appear to be radically different sets of capacities that humans possess as compared with other species (such generation of language and ability to abstractly and reflectively reason). Others emphasize the continuity of humans with other animals, suggesting that human beings differ from other animals primarily in degree of cognitive capacity (such as intelligence, conscious reflection, self-awareness, ability to use symbols and tools, and so forth).

Life and Death

Psychologists are not concerned with the origins of life generally. They typically consider individual life to begin with birth, but developmental psychologists sometimes use conception as the start-point for life especially when studying neonates that might have been born at different lengths of gestation. Psychologists generally see death as the endpoint of human development. Psychologists may, however, study conceptions of life, living things, and death and what happens after it.

Reality, Knowledge, Truth, Perception

These four concepts are interrelated in modern psychology. Generally, psychological science rests on realist epistemological foundations. Psychologists typically assume that human cognitive systems are such that they normally produce accurate knowledge about reality. They see perception as the principal process through which humans come to know reality through the senses. Though generally reliable, perception is not thought by psychologists to be error-free; on the contrary, much research in psychology describes

the biases that affect perception and the resulting disconnect between mistaken perception and reality or what is false and what is true. Similarly, conceptual biases and heuristics may lead to distortions regarding what is true and real (Gilovich 1991). Psychologists regard scientific methods and reason as tools for overcoming error and discerning truth.

Time

The concept of historical time is not important to psychologists. Psychological faculties are not assumed to have changed in significant ways through history. If, however, time is taken to mean duration, it becomes relevant to psychology. Reaction time, for example, is a commonly used indirect measure of the nature and complexity of cognitive processing.

Consciousness

Philosophers are more concerned than psychologists with the task of tracing the borders of the conscious and unconscious. Psychologists tend to use fairly commonsense understanding of these terms, often labeling “conscious” only those processes of which one has either awareness or which one can verbalize. For example, studies that involve priming, whereby a stimulus is shown to affect a response even when one has no awareness of it doing so, are often taken to be showing unconscious influences on behavior.

Rationality/Reason

Psychologists generally focus on how people do think and reason rather than whether they are rational or the nature of rationality. Nevertheless, psychologists do frequently contrast formal models of rational thought with actual practice. For instance, the work of a number of cognitive psychologists, including Nobel Prize winner Daniel Kahneman and Amos Tversky, has shown that humans do not always make decisions in accordance to rational economic principles, such as that of utility maximization (Kahneman and Tversky 1979). For example, people have often been shown to use heuristics, or rules of thumb, rather than rational analysis; to be influenced by irrelevant aspects of how problems

are framed; and to follow others’ behavior rather than assessing its appropriateness and utility.

Mystery

Scientific psychology attempts to eliminate mystery whenever possible, recasting mysterious phenomena as psychological problems that might be addressed empirically.

Relevant Themes

Perception

Cognitive psychology and related areas of cognitive science in part concern how people process information about their environment (or about their internal sensations) in order to understand what it is they are experiencing – the process of perception. Inasmuch as religious experiences require the representation and interpretation of either external or internal stimuli, the study of religious experience may be impacted by psychological understandings of perception generally.

Information Learning

One subarea of psychological science is how people acquire ideas and information – both from perceptual data and from communication. The dynamics of how ideas can be effectively shared bears upon religious education and communication. Further, when considering religious thought or practice, generally we are considering culturally shared thoughts or practices. The dynamics of how ideas are transmitted, and whether our cognitive systems are more or less receptive to certain kinds of information learning over others, may importantly shape which ideas spread widely and become adopted as religious (Boyer 2001). Applying such a cognitive perspective to the study of religion is a major emphasis of the area known as cognitive science of religion.

[Epistemology](#); [Truth](#)

Description

Coherentism comes in alethic and epistemic versions. As an alethic doctrine (the coherence theory

of truth), coherentism is an account of what it is for a proposition to be true. In this sense, coherentism is the theory that a proposition is true when it coheres with a system of beliefs. As an epistemic position (the coherence theory of justification), coherentism is a theory of what it is for a proposition to be justified. Coherentism in this sense is the view that one is justified in believing a proposition when it coheres with a system of beliefs. The two types of coherentism are often closely related since epistemic coherentism can be used to argue for a coherence theory of truth.

Epistemic Coherentism

Epistemic coherentism is the view that a proposition is justified by coherence with a system of beliefs (i.e., propositions held to be true), each of which is also justified by coherence with other beliefs in a system. In some versions of epistemic coherentism, justified beliefs cohere with the beliefs of some individual. In other versions, beliefs are justified by coherence with the beliefs of some community. Notable defenses of epistemic coherentism include BonJour (1985), Lehrer (1974) and Lehrer (2000). For a discussion see Kvanvig (2011).

One can be an epistemic coherentist about all propositions or only propositions in certain classes. A partial epistemic coherentist could hold, for example, that religious beliefs are justified by coherence with other religious beliefs (of some individual or community) without adopting a global coherentist account of how beliefs in general are justified. For a discussion of coherentism and religious belief see Plantinga (1986). Similarly, one can be an epistemic coherentist about moral beliefs without being a coherentist about other sorts of beliefs. Coherentism about moral beliefs is related to Rawls's view that a moral belief is justified when it stands in "wide reflective equilibrium" with other moral beliefs (Rawls 1971).

According to epistemic coherentism, justification is the result of a relationship among beliefs. This relationship may be described as mutual

inferential support. One belief in a system receives deductive or inductive inferential support from other beliefs and is consequently justified. These other beliefs can be inferred from still other beliefs and are justified. Eventually, all beliefs are supported by the others in a system.

Epistemic coherentism is motivated by a rejection of both foundationalism and skepticism. Epistemic coherentists believe that propositions can be justified, and consequently they reject skepticism. At the same time they reject foundationalism. Foundationalism is the view that beliefs can be identified which do not require justification because they are self-evident. These propositions are the foundation on which all other justified beliefs rest, that is, all other propositions are justified by reference to foundational propositions. In modern epistemology, the foundational beliefs have usually been thought to be beliefs about current experience. Coherentists believe that all propositions are in need of justification. In particular, they hold that beliefs about what is currently observed are in need of justification.

Contemporary epistemic coherentism emerged as a result of two failures of logical empiricism. The first was the failure of the logical empiricists to identify a class of observation (or “protocol”) sentences (propositions) that are not in need of justification. Neurath (1983) held that any proposition, even an observation sentence, can be rejected on the grounds that it is inconsistent with other propositions that are held to be true. The second was the failure of logical empiricists to show how all propositions, including universal generalizations (which are common in science) and propositions about the past and future, can be justified by appeal to foundational beliefs about what is currently observed. Neurath used his image of rebuilding a ship while it is at sea to illustrate his view that the justification of any belief is provided by other beliefs. Any belief can be part of the ship (i.e., the system of beliefs) or excluded from it, so long as adjustments are made elsewhere in the ship that enables it to remain afloat (i.e., it enables people to navigate the

world). A similar position was adopted by Quine. See Quine (1960) and Quine and Ullian (1970).

Some epistemologists have developed theories that are designed to combine features of foundationalism and coherentism. See, for example, the foundherentism of Haack (1993). Haack believes that a satisfactory epistemology must have a place for the justification of empirical beliefs by experience (as does experiential foundationalism). She also holds that justification often takes the form of beliefs mutually supporting each other.

Alethic Coherentism

The coherence theory of truth provides an alternative to the correspondence theory of truth, the pragmatic theory of truth, and the various deflationary theories of truth. Coherentism in this sense is, like the correspondence and pragmatic theories of truth and unlike deflationary theories, a substantive theory of truth. As a substantive, non-deflationary theory of truth, alethic coherentism states that truth is a property of propositions. In particular, it is the property of being true when it stands in the relation of coherence to a system of beliefs.

Several accounts can be given of system of beliefs with which true propositions cohere. On one account, true propositions are those which cohere with some actual system of beliefs. On another account, true propositions cohere with some ideal system of beliefs. This ideal system could be the system of beliefs adopted, at some ideal limit of inquiry, by being with the cognitive capacities of humans. Alternatively, the ideal system could be that of a being or beings with greater cognitive capacities than humans. In particular, the ideal system of beliefs could be that of an omniscient being, that is, God.

Two sorts of consideration have led philosophers to adopt a coherence theory of truth. In the first instance, some philosophers have been attracted to alethic coherentism by metaphysical considerations. A correspondence theory of truth depends on a distinction between beliefs

(i.e., propositions held to be true) and what makes beliefs true. Certain forms of idealism suggest that only beliefs exist. This leads to the view that truth must be the result of a relationship among beliefs. Walker (1989) attributes a coherence theory of truth to Spinoza, Kant, Fichte, and Hegel. Some British Idealists adopted alethic coherentism in the last years of the nineteenth century and the first decades of the twentieth. See, for example, F.H. Bradley (1914).

Epistemological considerations have also motivated philosophers to adopt a coherence theory of truth. Blanshard (1939) believed that a coherence theory of truth follows from a coherence theory of justification. He takes epistemic coherentism to be correct and the coherence of a proposition with a system of beliefs to be a reliable test of its truth. However, Blanshard suggests, if truth consists in correspondence to reality, there is no reason for coherence with a system of beliefs to be a reliable test of truth. He concludes that the truth of a proposition consists in its coherence with a system of beliefs. Rescher (1973) holds that this argument only succeeds if coherence with a system of beliefs is an infallible test of truth (which he denies). Otherwise, a belief could be justified but not true.

The alethic coherentist needs to provide an argument for believing that a proposition is true when it is justified by coherence with a system of beliefs. Anti-realism of the sort defended by Dummett (1978) can be used to defend the conclusion that truth is to be identified with what is justified (or warrantably assertable, as Dummett says). This argument would start from the premise that the meaning of a proposition consists in its truth conditions. Suppose then, for the sort of reasons Dummett advances, that the meaning of any proposition consists in the conditions under which it is warrantably assertable (or justified). It follows that the truth conditions of any proposition are the conditions under which it is justified. If the conditions under which a proposition is justified are the conditions under which it coheres with a system of beliefs, and the conditions under which a proposition is true are the conditions under which it is justified, alethic coherentism

ensues. For this sort of argument see Young (1995). In that the coherence theory of truth links the concept of truth to the concept of what can be justified (or warrantably assertable), and alethic coherentism has an epistemic conception of truth.

The relation of coherence, as employed in the coherence theory of truth, is closely related to the relation of coherence employed by epistemic coherentism. That is, according to the alethic coherentist, a proposition coheres with a system of beliefs (and is true) when the proposition can be deductively or inductively inferred from beliefs in the system.

Once the coherence theory of truth is stated in these terms, it becomes vulnerable to two standard objections. The first of these may be called the specification problem, which can be traced to Russell (1907). The specification problem challenges the alethic coherentist to specify the system of beliefs with which true propositions cohere without presupposing a non-coherentist conception of truth. Initially the problem is that there is any number of equally consistent sets of propositions. Many propositions will cohere with one of these systems without being true. For example, the proposition that Alice slew the Jabberwocky coheres with a possible set of propositions, but is not true. The alethic coherentist can respond that the system of propositions with which true propositions cohere is a set of propositions which is believed. If coherentist adopts this position, the specification problem reemerges in another form. Walker (1989) argues that the proposition that some set of propositions is the one that is believed can only be true because, as a matter of fact, people believe it. But then there is a proposition (namely, the proposition that a specified set of propositions is believed) which is true because of a relation to matter of fact, not as a result of a relation among propositions. This is contrary to the coherence theory of truth.

The second standard objection to the coherence theory of truth may be called the transcendence problem. According to this objection, truth transcends what coheres with any system of

beliefs. This position can be motivated by considering examples of propositions which are apparently true but which do not cohere with any actual system of beliefs. Consider the proposition that there is an even number of stars in the universe. Either it or its negation, by the law of excluded middle, is true. Nevertheless, neither the proposition nor its negation coheres with any system of beliefs. Proponents of the transcendence problem conclude that a proposition can be true even though it does not cohere with a system of beliefs.

Some versions of alethic coherentism are immune to the transcendence problem. If truth is coherence with the beliefs of an omniscient being, the objection fails since every truth coheres with the set of beliefs of an omniscient being. However, some versions of alethic coherentism hold that the truth of a proposition consists in coherence with a system of beliefs which finite knowers hold or could hold. These versions of the theory must cope with the transcendence problem. Alethic coherentists can defend their position against the transcendence objection by maintaining that the objection begs the question. Those who present the objection assume that it is possible that some proposition be true even though it does not cohere with any set of beliefs. This is precisely what advocates of the coherence theory of truth deny. Coherence theorists have arguments for believing that truth cannot transcend what coheres with some set of beliefs. Their opponents need to take issue with these arguments rather than simply assert that truth can transcend what coheres with a specified system.

Both epistemic and alethic coherentism continue to find defenders among contemporary philosophers. Epistemic coherentism is more widely held, but the coherence theory of truth also has advocates.

Description

(1) A complex concept. (2) Theories. (3) Analytical approaches. (4) Social Movements. (5) Dynamics. (6) Future perspectives.

A Complex Concept

Collective Behavior, unlike other concepts in social science, is very wide, complex, and difficult to define. It includes different behaviors, structures, processes, and contexts. Many areas of sociology and psychology, as well as economics and political science, involve the study of Collective Behavior, often restricting the focus to particular types of it such as religious, political, deviant behavior, and others.

The concept of Collective Behavior does not define a group of social phenomena which can be objectively verifiable, but can be intended as a reference to understand different sociological orientations, which sometimes converge, and sometimes contrast.

Originally called “mob behavior” or “mass hysteria,” Collective Behavior was believed to occur when people lose their ability to reason, and become temporarily insane. The perception of Collective Behavior has changed, and researchers today are aware of the fact that it concerns many types of social events which include fads and rumors, millennial movements, social movements, miracles and religious sightings, and other occurrences, not necessarily related to violence or brutality.

Collective Behavior is a fascinating social phenomenon that cannot be restricted to a specific type of social, political, psychological, economic process or behavior, because it is wider, multifaceted, and inclusive. Concisely, the concept of Collective Behavior can be defined as a response to problematic situations and circumstances.

The studies on Collective Behavior focus on the motivations, the modalities, and the dynamics that characterize the evolution of this response, and refer to the spontaneous manifestation of behavioral patterns as well as to organized social movements. Among all these modalities, there are riots, lynching, responses to natural disasters, panic, rumors, revolutions, and rebellions, a very wide range of situations and responses, that render Collective Behavior a term that covers a field without definite borders. While this constitutes its limits on the one hand, it is also a resource and an ongoing challenge on the other, because it leads to continuous redefinition and update.

The concept of Collective Behavior has changed and adjusted to the evolution of society, because being related to social rules and expectations, when these change, it also changes. Moreover, the concept has broadened, because the advancements in technology and its diffused use, make Collective Behavior more incisive – it can even acquire a global dimension through social networks, for instance- and varied in its forms. Research on Collective Behavior has also changed and broadened, giving new impulse to its conceptualization – for instance on the crucial issue of what makes it different from other forms of group behavior – because there are new methodologies which allow a wider gathering of data, interdisciplinary approaches, equal application of both qualitative and quantitative methods, recognizing the fundamental contribution of both.

Collective Behavior’s great interest lies in its high cultural value, as it can explain important social phenomena, and because of its high concrete and practical value; studies on the dynamics of Collective Behavior can help prevent unrest, and violence; it can also help to plan and suggest strategies as to prevent and to react to natural disasters and human security consequences.

Theories

Gustave Le Bon in *The Crowd: A study of the Popular Mind* (1895) can be considered the initiator of the studies on Collective Behavior, as the earliest formulations of this concept are to be found in crowd psychology. He affirms that the crowd is a reality *sui generis*, which “forms a single mind and is subjected to the law of the mental unity of the crowds” sustaining that all individual responses are lost in crowds. His theory is known as “Contagion Theory,” and is based on the idea that episodes of violence are driven by animal-like instincts that spread through a “maddening crowd” like an infection.

Le Bon has strongly influenced Sigmund Freud, who in *Mass Psychology and the analysis of the Ego* (1921), integrates his theory with the idea that suggestibility does not constitute an explication in itself, but needs instead to be explained. He also affirms that the role of the leader within the crowd, and the relationship between the followers and the leader must not be underestimated, as he thinks Le Bon does. Freud explains group participation by applying psychoanalytic theories of the instinct-object relationships in the individual and of the primal horde.

The post First World War period inspired many European theorists at that time, as the restoration of peace had not produced a climate of social and political serenity. The events occurred in Russia, with the Bolshevik Revolution, for instance, reinforced the workers’ movement, but at the same time increased the fear of a potential affirmation of socialism in the rest of Europe. In the 1930s, many social movements of different orientations emerged, eventually leading to the advent of totalitarian regimes. The crowds became “organized masses”. The studies follow the evolution of these historical events, and focus on the explanation of the instinct that guides the masses and influences the situation in Europe. Studies, such as *The revolt of the Masses* by José Ortega y Gasset (1930), *The Mass Psychology of Fascism* by Wilhelm Reich (1933), and *The rape of the Masses* by Serghej Ciacotin (1938), express this profound need of understanding the new social reality.

During this time, in the United States, the behaviorist theories became very successful, with a consequent growing need to study social phenomena with a more concrete and less theoretic approach. The first result of this new trend is that the issues related to these fields of studies became fragmented into different fields, which advance in parallel, among which emerged the new sociological field that will eventually be recognized as Collective Behavior.

The Chicago School distances itself from the rigid stimulus–response mechanism, stressing instead the mutual influence and the continuous exchange between individual and social environment. Robert Park, along with Ernest Burgess redefines the “Contagion Theory.” In *Introduction to the Science of Sociology* (1921), Park uses the expression “Collective Behavior” for the first time. Collective Behavior is defined as the behavior of individuals under the influence of a common impulse, which is the result of social interaction. Social unrest, sects, social contagion, mass movements, propaganda, fashion, and crowd mind are defined as Collective Behavior. This theory has constituted the main reference for decades, as the studies on this concept are few and have been carried out by almost exclusively those who studied under Park. Amongst them, Herbert Blumer (1951) has studied social processes and events saying that they do not reflect an existing social structure but emerge in a spontaneous way. He has developed the theory of the “acting crowd,” that is an excited group animated by a common goal. Blumer identifies five steps that turn a group of individuals into an acting crowd: social unrest, exciting event, milling, common object of attention, and common impulses.

In the 1950s, a process starts that will lead in the following decades to a progressive reinterpretation of these kinds of social phenomena, considering them less abnormal, not all motivated by irrational, violent, or hysterical behavior. The process has contributed to individuate and underline the similarities between collective and institutionalized behaviors. The “Contagion Theory” could not explain mild expressions of Collective Behavior and events, such as those related to

fashion, for instance. New theories and interpretations were needed.

Within the interactionist tradition – as in *Collective Behavior*, a study by R. H. Turner and L. M. Killian (1957) – great importance is given to social typing and to the way in which role models are created and diffused in society. Turner and Killian elaborate the concept of “Emergent Norm Perspective,” which is a process: When people find themselves in a new and unknown situation, they must create new norms to adjust to the situation. The process is rational and logical, and explains that once everyone recognizes which behavior is appropriate to the situation, they adopt the behavior. Nevertheless, not all behaviors within a Collective Behavior episode are the same. Turner and Killian elaborate a classification schema in which participants are placed according to the motivations at the basis of their decision to take part in a collective event: They could be insecure, ego-involved, concerned, curious spectators, or exploiters. Each of these motivations is neither irrational nor insane. Whichever category the participant belongs to, his/her behavior will be rational as long as the individual will remain in that situation.

Neil Smelser has offered another sociological approach in *Theory of Collective Behaviour* (1963). His “value-added schema” suggests that the determinants of Collective Behavior are given by a sequence of events and elements: structural conduciveness; structural strain; growth and the spread of a generalized belief; precipitating factors; mobilization of the participants for action; operation of social control. The latter, Smelser sustains, is particularly important because it determines the duration and the severity of the episode of Collective Behavior. Smelser defines Collective Behavior as “a mobilization on the basis of a belief which redefines social action” (Smelser 1963: 8) and views it as episodes of group behavior that relieve some social strain.

Since the end of the 1970s, sociologists have tried to overcome the distinction between conventional behavior and Collective Behavior, aiming to identify convergences and divergences

between social behaviors within the same conceptual and theoretical structure.

The categories defined by nineteenth century theorists, who identify different aspects of Collective Behavior (crowd is a type of group; panic is an individual psychological state; etc.) have shown that the field of Collective Behavior is difficult to define because it pertains to different fields and subjects that find convergences only by chance or tradition. According to Marx and McAdam (1994), the theorists of the twentieth century have perpetuated very similar approaches in a rather uncritical way, not distancing themselves much from the original theories, with little innovation. In this way, the field can be seen as a residual category which is used to fill gaps in social analysis when an event cannot be studied as social structure or other. Marx and McAdam suggest that the “Social Movement” theory has moved too far in the direction of the “Collective Action” theory and too far away from the “Collective Behavior” theory.

It is interesting to note also that there are differences between the European and the American approaches to Collective Behavior, although the following general definitions must not be intended as definite categories. Post second World War American sociology has been dominated mainly by functionalism (the concept of “institution,” “integration,” “socialization”) and therefore, the concept of Collective Behavior – linked to that of “social movements” – has been introduced and acquired only with the emergence of the protests and organized movements which developed in the 1960s in the United States: the student movement, the Civil Rights movement, the protests against the Vietnam war, and others. The fact that these movements were characterized by the refusal of dominant values, and often recurred to violence, indicated, somehow unpredictably, that the mechanisms of social and cultural integration were weak and not responding to the new demands and needs.

Europe, on the contrary, has been influenced strongly by a Marxist interpretation of society according to which the social organization is

based on a conflict or on a relationship of subordination.

In the United States, Collective Behavior is interpreted as marginal and as the result of malfunctioning social integration mechanisms; in Europe, the Marxist interpretation tends to focus the analysis on opposite Collective Behaviors, which end up by depicting a dramatic image of history.

The different interpretations of the concept of Collective Behavior all share the idea that they are the expression of general dissatisfaction regarding a purely liberal vision of social life, which reduces society merely to market interactions. In fact, the specific feature of a market, above all when its mechanisms are not altered by coalitions, is that it favors a rational quest for individual interest. An "open" society would then be made entirely by individual stories, which could only be linked in statistical groupings. Stratification in these open societies can be relevant; nevertheless, it does not necessarily mean that individuals who belong to the same stratum would be able to organize Collective Behaviors. It is more probable, however, that they will share similar or common behaviors with regard to opinions, consumerism trends, and social mobility. This is the principle at the basis of opinion polls, which explains why they are largely diffused in western societies: They are considered able to propose a reliable model of individualized behaviors, which are then statistically categorized according to preferences.

All this suggests that there can be Collective Behavior only in societies which are not entirely open, or, as most theorists affirm, societies which are dominated by power, therefore operating according to the logic of domination.

Two opposite positions emerge from the studies: On the one hand, the most liberal interpretation, and the theory called "Methodological Individualism," underlines the limits of all the attempts to analyze Collective Behavior; on the other hand, all those who refer to Collective Behavior agree that a merely utilitarian and individualistic analysis of social behavior is not sufficient.

Analytical Approaches

There are various analytical approaches to Collective Behavior, which derive from the conceptual frameworks of the protection of interests, reform movements, and social movements.

The first approach is related to the individual self-interest. A traditional assumption in economic models of human behavior is that people behave exclusively in accord with their own self-interest. However, there is a growing appreciation that people are inherently social creatures, and that people often intrinsically care about the welfare not only of each other as individuals but also of the groups to which they belong.

The main analytical question regards how the protection of individual interests can lead to Collective Behavior. The answer can be found in the famous free-rider paradox by Olson (1965: 2): "(...) the individual in any large group with a common interest will reap only a minute share of the gains from whatever sacrifices the individual makes to achieve this common interest. Since any gain goes to everyone in the group, those who contribute nothing to the effort will get just as much as those who made a contribution (...) large groups, at least if they are composed of rational individuals, will not act in their group interest." Olson has observed, being a prominent representative of methodological individualism, that if individual interest is well understood, it must lead individuals to nonparticipation, rather than to participation in collective action. It would be more rational to let others take the responsibility and the costs of collective action (for instance, a demonstration, a strike) and then profit from the result without any involvement. Olson affirms that particularly in labor unions, this leads to the creation of very small negotiation units because this allows each individual to better understand which interest there would be in taking part in a collective action.

How do interest groups and collective actions develop? Olson finds the roots of this social phenomenon in the moment in history in which the unions and the mass political parties were formed in Europe at the end of the nineteenth century. Robert Michels, in his writings, explains this

clearly when he affirms that mass actions develop because they favor their leaders. Any political system evolves into an oligarchy that regulates all big organizations, even when they are defined as democratic, because they function in the interest of what is often defined as their techno-structure. Nevertheless, the leaders do not act as individuals on a market. They are positioned within a more circumscribed and organized world, the world of political leaders, in which they develop a power strategy which must assure the leader him/herself, that his strategy will convince his/her own supporters to believe it is specifically intended to favor their needs. This is why they recur to symbolic discourse and actions aimed at reassuring their supporters, although this might not be coherent with their actual behaviors.

This introduces the "Resource Mobilization" theory, which opposes the utilitarian approach by underlining the limits of interpreting Collective Behavior as only aimed at the protection of interests. This theory focuses on the ability of any social movement organization to successfully manage and acquire resources that could be constituted by anything that could favor or hinder the success of the movement (votes, media coverage and other). Leaders' actions show that between the demands of individuals and the responses, there are power relations, which means that it is not possible to oppose individual interests to the collective character of action: The goods the individual is aiming at are not on the market but depend upon the power centers, whether governments or enterprises. Very few social actors are able to fulfill their goals without forming alliances or coalitions and orient their victory toward more symbolic than material gains. This kind of analysis is very relevant, in particular when applied to specific issues such as labor unions activities.

Another approach is inspired by the hypothesis developed by functionalist sociologists based on the fact that they see the formation of Collective Behavior as the expression of malfunctioning institutional mechanisms. Collective Behavior would then be the opposite of

individual behavior based on the conformity to dominant norms which have been interiorized. In this sense, the most important Collective Behaviors are conformist, for instance, movements that are inspired by the dominant values in a given society.

Protest movements are present in all democratic states. They denounce injustice, the nonrecognition of the right of expression and action of specific groups. It is in fact the concept of "minority" that in the United States has given the most help to groups which were able to mobilize in the name of universal principles, of human rights. Modernization movements, for instance, are inspired by the idea of a natural evolution of history that requires that societies constantly reconsider the principles and the institutions on which they are based. These movements imply that reforms are believed to be possible and even probable. Otherwise, the mobilization loses its sense and violence can spread. Peace movements, civil rights movements, and many others have achieved important goals in fostering reforms. Reforms and the diffusion of democracy have been the central theme of the social-democratic regimes in Europe and of the British Laborism. The British are the first to have elaborated the concept of industrial democracy and of social pact, allowing for great collective agreements on social issues, in line with the shared principles in the political society.

It must be underlined that power relations, however, cannot explain all social collective reactions systematically, as the affirmation of the dictatorships in the twentieth century and its ruinous consequences demonstrate. Collective Behavior can be in fact strongly influenced by leaders who are gifted by an undefinable charisma, as Weber defines it, which legitimates their power. These leaders are able to persuade vast masses of people with a political discourse whose content – either in favor or against the mass – is disguised in a highly symbolic narrative that renders individuals acritical and inclined to be convinced.

Some of questions that these phenomena raise are still to be answered.

Social Movements

Another analytical approach to Collective Behavior is constituted by social movements. They are defined as an organized effort by a significant number of people to change (or resist change in) some major aspects of society.

While social movements are considered a form of Collective Behavior by many researchers, others affirm that they must be distinguished from it, because social movements are organized and structured, while Collective Behavior is random and chaotic. Nevertheless, they have become an important field of study on itself.

The Collective Behavior theories above mentioned can be applied to the analysis of social movements. Social movements are organized, are able to produce changes in society and to last for a long period of time. In *The Politics of Mass Society* (1959), Kornhauser sustains that social movements attract individuals who are socially isolated and perceive themselves as socially insignificant. Social movements give a sense of meaning to individuals, which renders them more social than political. The “Mass Society” theory of Kornhauser suggests that social movements mobilize more easily people with weak social ties, and are led by individuals who pursue their own social interest.

The analysis of social movements has also inspired the “Relative Deprivation” theory which is based on the assumption that social movements form when a group of people feels deprived of what they think is their right to have. Denton Morrison in *Some Notes Toward Theory of Relative Deprivation, Social Movements and Social Change* (1978) has applied this concept, originally elaborated by Stouffer in *Studies in social psychology in World War II* (1949). Morrison argues that when people are dissatisfied, believe to have a right to their goals, and believe that they will not be able to do so through conventional means, they will form a social movement to achieve those goals. The sense of unjust deprivation is a strong motivation.

Although the term “social movements” is widely used in sociology, it would be better defined in this context – to be used as an

analytical tool – as those Collective Behaviors that question, through a social conflict, the way in which a given society makes use of its resources and its cultural model. In this way, social movements in connection with Collective Behavior seem to privilege the conflict aspect, in direct connection with the concepts of protection of interests and interaction between individuals.

This analytical approach to Collective Behavior is quite demanding as it implies that there exists an underlying central conflict in a given society. Many studies have in fact stressed the existence of a fundamental conflict behind the apparent variety of social behaviors, proposing new forms of class division and class conflict.

The approaches to Collective Behavior above mentioned are not equally relevant. According to Alain Touraine, as he writes in *Le retour de l'acteur* (1984), the concept of social movements is to be put at the highest level. This level, that he calls *historicité*, is also the most difficult to reach, as it constitutes the social realization of the great cultural patterns through which a society builds up its relations with its environment. On the contrary, interest conflicts must be positioned at the level of the social organization and also at the level of what sociologists call “organizations.” Reform movements must be positioned between the two levels, together with institutions and political mechanisms, which produce a range of mediations able to lead social power relations to forms of professional or technical organizations.

Social movements, the highest level of Collective Behavior, can be formed only when the two other types of Collective Behavior – protection of interests and reform movements – which are positioned at social organization or at political level have been overcome. It is very important to take into account in the analysis that social behaviors must be identified and positioned at the right level of the social reality in which they act. The analysis of Collective Behavior through the social movements approach offers the advantage, by which it allows to stress this diversity, while often utilitarian analysis tends to refuse the existence of other types of Collective Behavior and thus refuses other kinds of analysis.

Dynamics

All social behaviors are based on common meanings and shared imagery, which allow for a collective definition of a situation. Individuals or groups decide to support new and disjunctive behavior in situations that are inherently unstable, where there is an element of choice, some novelty, a crisis, attrition, conflict, competitiveness which create a problem. These situations allow the development of Collective Behavior, which is dependent upon the feelings and experiences of the participants.

Choice implies the existence of alternatives and the opportunity to select them freely, but does not provide generally accepted criteria on which the selection can be based.

Novelty is created by situations that have not been experienced before by the participants. Crisis emerges in extraordinary situations, and in emergencies, which create new demands that constitute a test for organized groups or favors the creation of new ones. Attrition develops in the presence of a difficulty that weakens the collective effort. Competitiveness emerges when a rewarding structure – that could favor individual rather than collective solutions – influences a cooperative solution. Regarding conflict, it implies a power relation of dominion, with a party trying to impose a claim, while its legitimacy is challenged by another party.

In all these situations, imagery and meaning lose their collective dimension and can be questioned. In many problematic situations, different elements are present at the same time, each with its own dynamic which produces an episode definable as Collective Behavior.

One hypothesis is that groups of people create emergent patterns that have integrity of their own, and as a consequence that there are strong individual differences across different groups. Although it is possible to draw many convergences in the general patterns formed by people, it is important to stress the critical dimensions of variations.

The first element to analyze is the primary motivation of individuals. Given that individuals are not only moved by self-interest, but can care for the more general welfare, the interaction

among individuals determines the pattern of emergent groups. Forms of dialectical interaction include competition and cooperation, as well as a number of behaviors that are contingent upon the behavior of their peers. They imitate those behaviors or differentiate from them. Imitation is very important in diffusing innovation within a community, which is then assimilated. The choice between imitation and differentiation is often dynamic and depends upon the situation, and as with cooperation and competition, it implies elements of both, imitation and differentiation. The base motivations in the choice of the individual to take part in Collective Behavior or not are also related to the fact that the individual does not need to predict group level outcomes, as successful groups can emerge from individuals who are strongly motivated by self-interest.

Current research focusing on modeling Collective Behavior aims at systematizing the development of more effective ways not only to predict but to control collective outcomes. Even without instituting physical or abstract barriers, it may be possible to indirectly control Collective Behavior with substantial efficacy. According to this view, Collective Behavior is more controllable than the behavior of isolated individuals because of the strong influences among the individuals' behavior. This concept is at the basis of a new approach that intends to support effective collective organization, with the aim of allowing the formation of self-organized patterns rather than dictating high level structures in a system of top-down control. As Goldstone and Gureckis sustain (2009: 418): "this conceptualization of design planning as facilitating self-organization rather than dictating final form may have an important moral for social systems in general."

Future Perspectives

There has been in recent years a renewed interest in Collective Behavior, the reasons being many. First of all, the fact that there have been interesting developments in the formal modeling of Collective Behavior, which are playing an important role in sociology – as Macy and Willer (2002) and Cipriani (2005) stress – as well as in economics, psychology, and anthropology, has

increased interest in Collective Behavior. Second of all, research can now count on new empirical tools that have changed the way scientists approach the issue of Collective Behavior, as regards dynamics and patterns. They can now be measured and analyzed in new ways. For instance, the internet, mobile phones, specific software, and others allow the observation of large groups of people, and the formation of collective dynamics within them. Technology is playing a significant role in research as it allows the recording of the evolution of collective decision-making moments away, as in the Arab Spring where the web played a crucial role. Data can be gathered online from blogs, social networks, and others. Third of all, globalization has played a significant role, as it implies more and more connectedness, with consequent phenomena such as de-territorialization and others, among which, for example, the World Wide Web, that has been the object of many studies on nonlinear group dynamics.

These innovations seem to promise that Collective Behavior, in a world of collective ambitions, will be studied and observed more and more.

How Collective Behaviors will develop is difficult to predict, although some elements of the recent changes can be identified. First of all, Collective Behaviors are less directed to the political and cultural centers of power and are more focused on the defense of the autonomous actions of the actors, either in relation with the others, in relation to central powers, or in relation to external challenges and risks. Collective Actions in this sense require that the participation of their members is more responsible and individualized. Second of all, Collective Behaviors mobilize their actors completely, at all levels, with the consequence that there is a passage from actions increasingly instrumental to actions which are also increasingly demonstrative.

Collective Behaviors are now so pervasive that they appeal to private life, to aspects such as personality and culture, and not only to institutionalized forms of political life.

The actors and their relations have become the most important elements of analysis, having

powerfully imposed themselves, through the new media and other forms of participation, in the social arena. The changes in society put Collective Behavior at the center of the analysis, even replacing institutions, which are relegated to a specific position.

Never before have Collective Behaviors been as fascinating, dynamic social phenomena as they are today.

Combinatorial Explosion

Linda Sherrell

Department of Computer Science,
The University of Memphis, Memphis, TN, USA

A combinatorial explosion is a condition where the numbers involved in a problem rapidly increase until they are either unmanageable or cannot be computed within our lifetimes.

For example, suppose that we have a team of n members, and we want to find the total number of possible meetings that can be held, assuming that we need two or more members to hold a meeting. For example, if there are 3 members in the team, only 4 types of meetings can occur; however, for 5 members, the number increases rapidly to 1013, and it is actually about 11 million billion or 11 quadrillion possible types of meetings among a team with 50 members.

Combinatorics

Linda Sherrell

Department of Computer Science, The
University of Memphis, Memphis, TN, USA

Combinatorics is a subdiscipline of mathematics. Basic topics in combinatorics are permutations and combinations.

A permutation of a collection of items is a listing of the items in one possible order. For example, consider a team of three students named Cindy, Allen, and Betty. The number of permutations of this collection is $3! = 3 \times 2 \times 1 = 6$. In other words, there are three ways to select the first name; two ways to select the second name, and then only one name remains. The general formula is $n! = n \times (n-1) \times (n-2) \times \dots \times 3 \times 2 \times 1$.

A combination is a collection of items where order does not matter. For example, suppose a student team consists of the same three people named above. The number of meetings that a team can hold, where a meeting must have at least two members attending, is ${}_3C_3 + {}_3C_2$ or $1 + 3 = 4$ meetings. In other words, there are two kinds of meetings: 1) everyone attends and 2) two people attend, that is, one person is not present.

The general formula for a combination follows:

$${}_nC_k = n!/[k!(n-k)!].$$

Commodification of Religion

Alexander Darius Ornella

Department of Humanities/Religion, University
of Hull, Hull, United Kingdom

Commodification of religion refers to religious symbols becoming commodities, objects of consumption readily available in the “supermarket of religion,” in economic life, and the media landscape. It is a process of recontextualization of religious symbols, language, and ideas from their original religious context to the media and consumer culture. In this process, religious symbols become commodities, objects of consumption readily available in the “supermarket of religion” and the media landscape. The commodification of religion works on several levels. The two most obvious are the (often commercial) offers of blessings, prayers, etc.,

through the purchase of religious artifacts, books, figures, etc. The second important – and obvious – level is the attachment of religious values through a religious aesthetic to consumer products. Often, the commodification of religion is related to a loss of power to shape religious practices.

Comparative Neuroscience

Friedrich G. Barth
Department of Neurobiology, Faculty of Life Sciences, University of Vienna, Wien, Austria

Description

Comparative Neuroscience studies the nervous and sensory systems of animals widely differing in regard to their position in the phylogenetic system and ranging from those at the basis of metazoan evolution (coelenterates) to those most highly developed (vertebrates) (Bullock and Horridge 1965). Taking evolution for granted, *Comparative Neuroscience* is interested in the structures and general principles underlying nervous processes and functions throughout the animal kingdom (Kandel et al. 2012). It is likewise interested in the particularities and diversity of animal species and taxa adapted to vastly differing life styles and habitats.

Comparative Neuroscience is devoted to basic research and has always been a domain of

zoology. Most basic mechanisms and structures at work in nervous systems have been first described in invertebrate and lower vertebrate animals like earthworms, squids, snails, horse-shoe crabs, crayfish, and rays. Considering the limitations of experimental work on humans, the medical neurosciences (neurology) have always had an interest in animal work as well (FENS).

Modern *Comparative Neuroscience* has amply shown that there is a wealth of fascinating adaptations of animal nervous and sensory systems to their specific needs. These often are very different from our human needs. On the other hand, it also has been learned that the same basic principles have been at work since early evolutionary times and that brain functions, previously associated with the human brain only, do have parallels and precursors even in the so-called lower animals (Prete 2004).

A particular feature of *Comparative Neuroscience* like that of the Neurosciences in general is its openness for other disciplines such as genetics, informatics, physics, mathematics, chemistry, engineering, psychology, and others which has been a major source of its success and is also evident from its diversification into numerous subdisciplines.

Self-Identification

Comparative Neuroscience is part of the natural sciences, applying a rigorous experimental approach to test the validity of hypotheses and their likelihood of being correct or wrong. Its subdisciplines differ in regard to the methods/technologies they apply. These include neuroanatomy, neuroethology, neurogenetics, cytochemistry, electrophysiology, mathematical modeling, and others. Clearly, *Comparative Neuroscience* is not a religion.

Characteristics

Comparative Neuroscience has a basic interest in the diversity and in the adaptations of nervous and sensory systems of particular animals and

animal groups living in different habitats and showing different behavior and lifestyle. Obviously, then, it is closely related and associated with zoology. Apart from its interest in the diversity per se, *Comparative Neuroscience* uses its knowledge of this diversity in search of overarching principles ([Journal of Comparative Neurology](#); [Journal of Comparative Physiology A](#)).

Relevance to Science and Religion

The discourse between “Science” and “Religion” has been dominated on the religion/humanities side by the belief in an explicitly unique position of man in nature. Along these lines of thought the insistence on the uniqueness of the properties of the human brain has been prevailing. While the human brain indeed is likely to be the most complex of all brains, modern *Comparative Neuroscience* has amply demonstrated that so-called simple central nervous systems are capable of amazingly complex operations and there are justified doubts as to whether there are really any unique features of the human brain not found (not even in a more simple form) in animals. A huge amount of evidence has accumulated demonstrating how far even small-brained animals like flies and bees or a cephalopod mollusk are from being simple reflex machines and showing that their sensory and nervous systems represent their worlds in a surprisingly complex and rich way. As a consequence *Comparative Neuroscience* strongly suggests the importance of a less anthropocentric attitude than hitherto often seen on the side of the humanities.

Sources of Authority

The most important sources of authority are internationally recognized, peer-reviewed scientific journals, books, and review articles summarizing previously published original results, which have gone through a process of rigorous evaluation by experts in the corresponding fields of specialization.

Ethical Principles

The ethical principles are those of any natural science. There are guidelines published by various agencies for proper scientific conduct mainly aiming toward the prevention of scientific fraud. Importantly, in *Comparative Neuroscience*, animal care is a serious issue and in many countries there are strict regulations regarding the use of animals for experiments.

Key Values

The key value is the gain of knowledge and understanding of structures and functions in nervous and sensory systems, their evolution, adaptability, and role in behavior. In view of the evolution of life and the many commonalities in all nervous systems, *Comparative Neuroscience* also contributes substantially to the understanding of the human nervous system and senses, to cognitive processes, and their pathologic conditions.

Conceptualization

Nature/World

These terms have been defined in many different ways. From the point of view of a natural science, the shortest definition is, the material world and its phenomena, or the natural physical world, including abiotic and biotic nature and of course man.

Human Being

Human beings are biological beings and the product of evolution like all other animals. Speech and abstract thinking are particularly well developed but not basically unique capacities of the human brain.

Life and Death

Life evolved from simple abiotic origins about three billions of years ago and now manifests itself in organisms as diverse as bacteria, plants, fungi, and animals (which include the

vertebrates, mammals, and man). Life follows the laws of physics and chemistry and depends on physical and chemical processes. It always has an important historical aspect to be considered (ontogenetic and phylogenetic development/evolution). The question what life is must be considered a metaphysical question and not within the scope of *Comparative Neuroscience*. Like other biological disciplines *Comparative Neuroscience* studies the structure of living organisms and what they do, how they do it, and what the prerequisites and conditions for their existence are. Death is the cessation of the functions typical of living organisms (acquisition and assimilation of energy, metabolism, locomotion, etc.) and the recycling of the elements they are made of into a global ecological system. Death is a condition for the process of evolution.

Reality

Reality is the physical world around us including the rules governing it. *Comparative Neuroscience* as a subdiscipline of biology acknowledges the existence of a real world independent of our experience in which all life evolved and to which living organisms had to adapt in a way favoring fitness, which is their survival and reproduction.

Knowledge

Like in all other natural sciences, knowledge in *Comparative Neuroscience* is supposed to have an objective quality and be valid by virtue of the repeatability of experimental research results. Assuming that hypotheses can be disproved and falsified but never and entirely proved, much of the knowledge accumulated by science has to be considered preliminary and subject to change.

Truth

Truth is not a concept or subject in *Comparative Neuroscience* where facts and rules of reality are the main interest. Saying that something is true in *Comparative Neuroscience* would point to the agreement with fact and reality.

Perception

Perception and consciousness unfortunately have often been conflated. Modern research provided

evidence for access to knowledge without awareness. This finding asks for a revision of the assumption that perception and consciousness of perception are always inseparable. From the viewpoint of *Comparative Neuroscience*, information on the inside and outside world is a necessary condition for the existence of all living beings. Not surprisingly then we find sensory mechanisms of high refinement already in bacteria and unicellular protozoans, that is, in organisms without any neurons and nervous systems.

There is a rich diversity of sense organs and of sensory capabilities in the animal kingdom including many which are superior and alien to our own human experiences. Sense organs are often called the windows of the brain to the outside world. Likewise, they are the interfaces between an organism's environment and its behavior. However, these windows (and the processing/integration of the data provided by them) are all highly specialized, selective, and far from being fully transparent. Sensory systems rather provide the individual with information on small fractions of the physical world only, which are the biologically relevant ones (serving fitness). Man is no exception to this. Our brain is actively involved in constructing perceptions not only on the basis of actual sensory data but also on the basis of inherited concepts like time and space (constructed during developmental stages), individual experience, memory, attention, intentions, etc., to which consciousness and introspection have no access. In other words, what is perceived is not raw sensory data but abstractions from these.

The sensory worlds of animals and man are highly filtered and species-specific "biological" worlds. Clearly, a particular feature of humans is their ability to enormously expand their sensory range by the development and application of sophisticated instruments and scientific inquiry.

Time

The concept of time is most important in biology and thus also in *Comparative Neuroscience*. Living organisms are never static but characterized by their dynamics – by a permanent change

through time from individual development (ontogeny), adolescence, adulthood, aging, and death. Likewise, evolution cannot be thought without the time axis.

From a more neuroscientific point of view, time is of prime importance in the way information is handled by neurons and nervous systems. One example is the modulation of nervous signal (action potential) frequency serving as an ubiquitous code in all nervous systems. Another example is the temporal synchronization of the oscillatory activity of spatially separated assemblies of neurons in the mammalian brain and its assumed involvement in the coordination needed for higher cognitive functions. Memory as a road into the past (both conscious and unconscious), imprinting and action plans as a prospect of the future are central issues in the neurosciences as well and intrinsically a function of time.

Consciousness

See also under “[Perception](#).” Consciousness is a concept not well/fully understood in terms of *Comparative Neuroscience* and not even in terms of research on the human brain and of psychology. Its function is not clear yet. We are not aware of most operations of the brain and central nervous system. This not only refers to the simple and automatic operations but also to complex cognitive operations. Unconscious perception is a topic receiving increasing attention.

Rationality/Reason

Rationality and reason are foundations of the natural sciences and thus of *Comparative Neuroscience* as well. The most important tool on which rationality and the increase and understanding are based in the natural sciences is the experiment.

Mystery

Mystery refers to something secret or unexplainable and beyond the reach of human comprehension. In *Comparative Neuroscience*, there is a lot still to be explained. However, this is not equivalent to saying that there are mysteries which are unsolvable in principle and will not be explainable in a rational, reasonable, and

logically valid way forever. Like all science, *Comparative Neuroscience* has turned lots of “mysteries” into marvels. The question of how minds with deep insights into the nature of matter and life and abstract mathematics could evolve from lifeless and mindless beginnings will still keep *Comparative Neuroscience* busy for a long time to come.

Relevant Themes

Comparative Neuroscience has revealed many achievements of animal brains hitherto attributed to humans exclusively. For the Science-Religion debate it seems appropriate to look upon mankind as one among many parts forming a complexly ordered world where a less anthropocentric, more rational, systems-oriented attitude in regard to what we are and are entitled to do is more appropriate than naïve and devastating arrogance.

Competitive Coherence

Victor Norris

Department of Biology, University of Rouen,
Mont Saint Aignan, France

Biological systems on all scales are confronted with the challenge of obtaining a future state that is coherent with environmental conditions and with previous states. These states are created by the active functioning of a set of constituents of the system. This *active* set is selected from the larger set available to the system. Many social organizations are constrained by the need to reconcile coherence with their present environment and coherence with their past environments. To grow and survive, research laboratories, for example, have to select an active set of workers in response to new discoveries and to new funding initiatives but must reconcile this selection with the research history of the laboratory and, in particular, with its skills, experience, and interests. To grow and survive, bacteria must also select an active set of macromolecules in response to external and internal conditions. Such responses entail both the generation of a coherent cell state, in which the cell's contents

work together efficiently and harmoniously, and the generation of a coherent sequence of cell states. Contradiction and incoherence are punished since a cell that simultaneously induces the expression of genes for growth at high temperature and at low temperature is likely to be out-competed by rival cells that induce each set of genes only when needed. A cell that proceeded from one cell state to another very different one (without good environmental reason) would be wasting precious resources. A strong selective pressure, therefore, exists to generate active sets of constituents to provide both coherent cell states and a coherent sequence of such states. We have proposed that *competitive coherence* is responsible for generating these active sets (Norris and Norris 1998). This concept is based on the way a system must maintain both the continuity of the composition of its active set via a *Next* process and the coherence of this active set (with respect to the inside and outside world) via a *Now* process. In one *in silico* implementation of this concept, the state of a system at time $n + 1$ is determined by a competition between the Next process, which is based on its state at time n , and the Now process, which is based on the developing $n + 1$ state itself (Norris et al. 2012). In the case of amateur football, consider the problem of selecting the team (the active set) each week from a larger group of potential players. A Next process might be the tendency for someone who plays this week to be someone who plays next week (it is, for example, easier to arrange shared travel with those already present). A Now process might be the coherence of the team with respect to itself (the team must have a goalkeeper, defenders, and attackers) and with respect to its opponents (who might be particularly brutal). As the new team is being chosen, the Next process gives way in importance to the Now process. *Competitive coherence* also operates at the higher level of the football league itself: a Next process results in teams that are in the league in one season being likely to be in it the next season, while a Now process results in a coherent league with teams of the same level dispersed over a certain geographical region.

In the case of bacterial organization, competitive coherence selects a particular *hyperstructure* (Norris et al. 1999) within a bacterium (such hyperstructures include multi-macromolecule assemblies responsible for ribosome synthesis, chemotaxis, sugar metabolism, etc.); a Next process allows those genes that are already expressed as part of a hyperstructure to help determine which genes are expressed next in a hyperstructure; a Now process then allows those genes that are starting to be expressed together in a hyperstructure to recruit related genes to the hyperstructure. *Competitive coherence* also operates at the higher level of the bacterial cell itself such that the state of a cell at any one time corresponds to the set of hyperstructures present within it. A new cell state is the result of (1) a Next process whereby the current active set of hyperstructures in the cell determines the next active set and (2) a Now process whereby the developing set of hyperstructures progressively recruits, maintains, or dismisses hyperstructures. Competition between these two processes ensures a sequence of sets of hyperstructures (cell states) that optimize growth and/or survival.

Emergent properties resist attempts to predict or deduce them (Van Regenmortel 2004). In the framework of *competitive coherence*, emergence is related to the selection of the subset of constituents that are active together (Norris et al. 2005). Suppose each constituent has a large number of characteristics (as in the case of macromolecules, such as mRNA and proteins, which contain a large number of sites that can bind water, ions, molecules, and other macromolecules). As proteins are being chosen via competitive coherence to work together, suppose that the first ones to be chosen just happen to contain a binding site to the same molecule. Suppose that, in some environments, this combination of proteins proves useful. Suppose too that this molecule becomes available, perhaps for the first time. The presence of this binding site could then become an important factor in the coherence process which dominates the choice of the rest of the proteins to work together in the active set. In other words, the environment acts via the coherence process to lend importance to one out of many sites.

The result is the selection of this site (plus the molecule that binds to it) as a determinant of the cell's response to a particular environment. More specifically, consider, for example, that (1) this binding site is for a particular phospholipid with long, saturated acyl chains and (2) the proteins with this site bind to the phospholipid to form a domain in which they are juxtaposed and in which their activities complement one another. There might then be a selection for this binding site in other complementary proteins. In the language of *competitive coherence*, binding to this phospholipid would become a type of connectivity to determine membership of an active set, and this active set would take on the physical form of a proteolipid domain responsible for a particular function. Hence, emergence in the context of *competitive coherence* can be understood in terms of a new criterion for membership of the active set.

Competitive coherence is a scale-free concept that is thought to operate at levels ranging from macromolecular assemblies to social groups. The nature of the Next and Now processes varies with the level. At the level of bacteria, these processes take the form of site-binding, DNA supercoiling, transcription factors, ion condensation, etc. At the level of human groups, these processes include the *mafia* and *status quo* pressures that are familiar to us all. Could *competitive coherence* operate at higher levels still? And if it were to operate, what form would the Now and Next processes take and what would be the consequences? One exotic candidate is subjective experience, the role of which remains controversial. A role for subjective experience in Now and Next processes at the level of ecosystems might be of general interest. Indeed, such a role would underpin speculations that our world itself is "conscious" (Norris 1998).

Completeness

Xavier Caicedo

Department of Mathematics, Universidad de los Andes, Bogotá, Colombia

Gödel completeness theorem claims that formal deduction in first-order logic coincides with semantic consequence. It may be taken as proving the purely analytical character of (first-order) universal truths and the possibility of reaching them in a purely mechanical way. It bears also on the existence of non-self contradictory objects. Its original form says that the formal consistency of a (countable) first-order theory

grants the existence of a (countable) mathematical structure realizing whatever the theory describes. Actual completeness and other key model theoretical properties of first-order logic like compactness, and the Löwenheim-Skolem theorem (shown originally by Löwenheim 1915) follow immediately. Uncountable versions of these results were obtained independently by A. Malcev (1941), A. Robinson (1948), and L. Henkin (1949). Their fruitfulness and the fact that these results failed for higher-order logics determined the primacy of first-order logic in further development of the model theory.

Complex Systems

Klaus Mainzer

Department of Philosophy of Science, Technical University of Munich, Munich, Germany

Related Terms

[Computer science](#); [Dynamical system](#)

A *dynamical system* is characterized by its *elements* and the *time-depending* development of their *states*. A dynamical system is called *complex* if many (more than two) elements interact in causal feedback loops generating unstable states, chaos, or other kinds of attractors. The states can refer to moving planets, molecules in a gas, gene expressions of proteins in cells, excitation of neurons in a neural net, nutrition of populations in an ecological system, or products in a market system (Mainzer 2007). The *dynamics* of a system, that is, the change of system states depending on time, is mathematically described, for example, by *differential equations*. A *conservative* (Hamiltonian) system, for example, an ideal pendulum, is determined by the reversibility of time direction and conservation of energy. *Dissipative systems*, for example, a real pendulum with friction, are irreversible.

In classical physics, the dynamics of a system is considered a *continuous process*.

But, continuity is only a mathematical idealization. Actually, a scientist has single observations or measurements at discrete-time points, which are chosen equidistant or defined by other measurement devices. In discrete processes, there are finite differences between the measured states and no infinitely small differences (differentials) which are assumed in a continuous process. Thus, discrete processes are mathematically described by *difference equations* or data given in *time series*.

Random events (e.g., Brownian motion in a fluid, mutation in evolution, innovations in economy) are represented by additional *fluctuation terms*. *Classical stochastic processes*, for example, the billions of unknown molecular states in a fluid, are defined by time-depending differential equations with distribution functions of probabilistic states (Scott 2005). In *quantum systems* of elementary particles, the dynamics of quantum states is defined by Schrödinger's equation with observables (e.g., position and momentum of a particle) depending on *Heisenberg's principle of uncertainty*, which allows only *probabilistic forecasts* of future states.

Historically, during the centuries of classical physics, the universe was considered a deterministic and conservative system. The astronomer and mathematician P.S. Laplace (1814), for example, assumed the total computability and predictability of nature if all natural laws and initial states of celestial bodies are well known. The *Laplacean spirit* expressed the belief of philosophers in determinism and computability of the world during the eighteenth and nineteenth centuries.

Laplace was right about *linear* and *conservative dynamical systems*. In general, a *linear relation* means that the rate of change in a system is proportional to its cause: Small changes cause small effects while large changes cause large effects. Changes of a dynamical system can be modeled in one dimension by changing values of a time-depending quantity along the time axis (*time series*). Mathematically, linear equations are completely computable. This is the deeper reason for Laplace's philosophical

assumption to be right for linear and conservative systems.

In systems theory, the *complete information* about a dynamical system at a certain time is determined by its *state* at that time. The state of a complex system is usually determined by more than two quantities. Then, a higher dimensional phase space is needed to study the dynamics of a system. The *phase space* of a system contains the *complete information of its past, present, and future behavior from all initial conditions*. From a methodological point of view, time series and phase spaces are important instruments to study systems dynamics. At the end of the nineteenth century, H. Poincaré (1892) discovered that celestial mechanics is not a completely computable clockwork, even if it is considered as a deterministic and conservative system. The mutual gravitational interactions of more than two celestial bodies ("Many-bodies-problem") can be represented by causal feedback loops corresponding to *nonlinear* and *non-integrable equations* with *instabilities* and *irregularities*. In a strict dynamical sense, the *degree of complexity* depends on the *degree of nonlinearity* of a dynamical system (Mainzer 2005). According to the Laplacean view, similar causes effectively determine similar effects. Thus, in the phase space, trajectories that start close to each other also remain close to each other during time evolution. By contrast, dynamical systems with *deterministic chaos* exhibit an exponential dependence on initial conditions for bounded orbits: the separation of trajectories with close initial states may increase exponentially.

Thus, tiny deviations of initial data may lead to exponentially increasing computational efforts for future data *limiting long-term predictions*, although the dynamics is in principle uniquely determined. This is known as the "*butterfly effect*": initial, small, and local causes may soon lead to unpredictable, large, and global effects. According to the famous *KAM-Theorem* of A.N. Kolmogorov (1954), V.I. Arnold (1963), and J. K. Moser (1967), trajectories in the phase space of classical mechanics are neither completely regular, nor completely irregular,

but depend sensitively on the chosen initial conditions.

Dynamical systems can be *classified* on the basis of the effects of the dynamics on a region of the phase space (Haken 1993). A *conservative system* is defined by the fact that, during time evolution, the volume of a region remains *constant*, although its shape may be transformed. In a *dissipative system*, dynamics causes a *volume contraction*.

An *attractor* is a region of a phase space into which all trajectories departing from a certain set of initial conditions, the so-called *basin of attraction*, will converge. There are different kinds of attractors. The simplest class of attractors contains the *fixed points*. In this case, all trajectories of adjacent regions converge to a point unchanged by the dynamics of the system. An example is a dissipative harmonic oscillator with friction: the oscillating system is gradually slowed down by frictional forces and finally come to a rest at an equilibrium point.

Conservative harmonic oscillators without friction belong to the second class of attractors with *limit cycles*, which can be classified as being periodic or quasiperiodic. A *periodic orbit* is a closed trajectory into which all trajectories departing from an adjacent region converge. For some simple dynamical system with only two degrees of freedom and continuous time, the only possible attractors are fixed points or periodic limit cycles. An example is a Van der Pol oscillator modeling a simple vacuum tube oscillator circuit.

In continuous systems with a phase space of dimension $n > 2$, more complex attractors are possible. Dynamical systems with *quasiperiodic limit cycles* show a time evolution, which can be decomposed into different periodic parts without a unique periodic regime. The corresponding time series consist of periodic parts of oscillation without a common structure. Nevertheless, closely starting trajectories remain close to each other during time evolution. The third class contains dynamical systems with *chaotic attractors* which are *non-periodic*, with an *exponential dependence on initial conditions* for *bounded*

orbits. A famous example is the chaotic attractor of a Lorenz system simulating the chaotic development of weather caused by local events, which cannot be forecast in the long run (*butterfly effect*).

Measurements are often contaminated by unwanted noise that must be separated from the signals of specific interest. Further on, in order to forecast the behavior of a system, the development of its future states must be reconstructed in a corresponding phase space from a finite sequence of measurements. Thus, *time series analysis* is an immense challenge in different fields of research from, for example, climatic data in meteorology, ECG-signals in cardiology, and EEG-data in brain research to economic data of economics and finance. Beyond the patterns of dynamical attractors, *randomness* of data must be classified by statistical distribution functions (Nakamura 1997).

Typical phenomena of our world, such as weather, climate, the economy, and daily life, are much too complex for a simple deterministic description to exist. Even if there is no doubt about the deterministic evolution of, for example, the atmosphere, the current state whose knowledge would be needed for a deterministic prediction, contains too many variables in order to be measurable with sufficient accuracy. Hence, our knowledge does not usually suffice for a deterministic model. Instead, very often a *stochastic approach* is more situated. Ignoring the unobservable details of a complex system, we accept a lack of knowledge. Depending on the unobserved details, the observable part may evolve in different ways. However, if we assume a given probability distribution for the unobserved details, then the different evolutions of the observables also appear with specific probabilities. Thus, the lack of knowledge about the system prevents us from deterministic predictions, but allows us to assign probabilities to the different possible future states. It is the task of a time series analysis to extract the necessary information from past data.

Complex models contain nonlinear feedback, and the solutions to these are usually obtained by

numerical methods. *Statistical complex models* are data driven and try to fit a given set of data using various distribution functions. There are also hybrids, coupling dynamic and statistical aspects, including deterministic and stochastic elements. *Simulations* are often based on computer programs, connecting input and output in nonlinear ways. In this case, models are calibrated by training the programs, in order to minimize the error between output and given test data.

In the simplest case of statistical distribution functions, a Gaussian distribution has exponential tails situated symmetrically to the far left and right of the peak value. *Extreme events* (e.g., disasters, pandemics, floods) occur in the tails of the probability distributions. Contrary to the Gaussian distribution, probabilistic functions $p(x)$ of heavy tails with extreme fluctuations are mathematically characterized by *power laws*, for example, $p(x) \sim x^{-\alpha}$ with $\alpha > 0$. Power laws possess scale invariance corresponding to the (at least statistical) *self-similarity* of their time series of data (Mandelbrot 1997). Mathematically, this property can be expressed as $p(bx) = b^{-\alpha}p(x)$ meaning that the change of variable x to bx results in a scaling factor independent of x while the shape of distribution p is conserved. So, power laws represent *scale-free complex systems*. The Gutenberg-Richter size distribution of earthquakes is a typical example of natural sciences. Historically, Pareto's distribution law of wealth was the first power law in the social sciences with a fraction of people presumably several times wealthier than the mass of a nation.

[Algorithmic complexity](#); [Program complexity](#)

Computational complexity theory is a subdiscipline of computer science and mathematics that tries to classify computational problems and mathematical problems according to their difficulty. In this context, a computational

problem or mathematical problem is understood to be a task that could be amenable to being solved by a computer (which means that the problem can be stated by a set of mathematical instructions).

Computational Memories

Andrew J. Neel and Max H. Garzon
Department of Computer Science,
The University of Memphis, Memphis, TN, USA

Related Terms

[Biologically based computers](#); [Computer memories](#); [Electronic memories](#); [Magnetic storage](#)

Description

A computational memory is any device that allows for storage of data for later retrieval. Flash disks are common examples today. Like its counterparts in biology, the quality of a memory is measured by its capacity (how much data it holds), speed (how quickly data is recalled), reliability (how long data is retrieved with a consistent result), and meaningfulness (the correctness or relevance of retrieved information.)

Memory is frequently assumed to be equivalent with random access memory (RAM) in modern computers. However, memories definition more properly includes RAM as well as CDROMs, DVDs, floppy disks, USB drives, ZIP Drives, hard disks, and other types of conventional storage. That said, the definition of memory is also broad enough to include storage devices as simple as an abacus which uses beads to store information. In the past 50 years, computer systems have moved from ferromagnetic

cores (1940s), to tape drives (1950s–1970s), to magnetic disks (1980s), to optical disks (1990s), to ► [artificial neural networks](#) (1990s–2000s).

The most recent developments have been the exploration of information retrieval from memories conceived and implemented in entirely different ways. Hopfield memories, which are specialized artificial neural networks focused on pattern recognition and memory (Hopfield 1982) exhibit retrieval and error-correcting capabilities resembling characteristics of human memory and suggesting a plausible explanation of how these characteristics might be working inside the human brain. Associative memories and Baum memories further model human memory recall by using synthetic Deoxyribonucleic Acid (DNA) to implement associative recall akin to recall in human memory. The motivation for DNA is the real feasibility of creating a computational memory which simultaneously stores and processes data. Such computational memories are believed capable of solving problems considered extraordinarily difficult using conventional solutions which separate data storage and data processing. Computational memories were demonstrated by Adleman (1994) when he used DNA to solve the Hamiltonian path problem using DNA as both processors and storage. As a result of his work, it was believed that computational memories could be used to solve even routine tasks easily. The application of DNA as a computational memory for routine tasks has since shifted toward the use of DNA for special-purpose nanodevices for specific applications. Both the original and new visions still require memory systems for DNA computers capable of either sophisticated processing capabilities, such as self-assembly of DNA into useful molecular structures (Seeman 1999; Winfree et al. 1998), or capable of storing, in principle, large amounts of data (order of terabytes) for information retrieval (Baum 1995). Neel (2007) explored the issues and ultimately demonstrated a process for semantic retrieval from memories with speeds, reliability, and scalability exceeding the best conventional counterparts of the time.

Self-identification

Science

The science of computational memories is the study of how to build devices that store data for later retrieval, how to store data, and how to later retrieve that data in some useful and effective way. This discipline uses scientific methods to study every aspect and example of storage and retrieval available to us. For example, artificial neural networks have shown how the brain encodes information in the networks of relatively simply but massively parallel neuron-like units for later recognition and retrieval in a content-addressable way. Likewise, DNA is a natural memory that can be used to build a human body by decoding instructions stored in base chemical chains into complex mechanical, computational, and chemical systems. In the same way, memory technologies developed for stand-alone computers have been studied to help understand how large distributed computer systems could be built. These studies have led to new ways of thinking about text searches, image matching, automated question-answering, and other problems. They have also enabled us to amass an immeasurable amount of data in a highly distributed system called the Internet for recall from anywhere in the world.

Characteristics

The study of memories is unique because it frequently interfaces with a broad range of other disciplines before tying the result of that study into advancements in memory systems. For example, today's computer systems require electrical engineers to build the computer circuits for a random access memory or hard drive. These same memories require specialists to determine the best materials to use in each part. Again, these same systems require advanced mathematics to help detect errors, to identify the fastest method of memory recall, and to catalog massive amounts of data. Library scientists study methods of keeping records of the data stored in memories. Linguists and language specialists are necessary

to determine how to get the most useful information from massive data stores. Beyond the conventional computer, medical doctors, neurologists, psychologists, and chemists may get involved in understanding how the human brain works to recall data and transform it into information. Chemists and biologists must participate to help understand how the DNA stores and retrieves information to form a human body. Computer scientist must take ideas and models from each discipline to glue them together in ways that improve computer memories. Therefore, computer scientists very uniquely support other fields in producing new results while simultaneously consuming much of the product of that work.

Relevance to Science and Religion

Scholarly areas of science and religion study their particular discipline in order to produce new data and new information. Many of these disciplines have centuries of work behind them. Consequently, each discipline is in urgent need of memories capable of storing the full suite of data for that discipline and enabling quality retrieval and analyses of that data when properly queried. The use of computer memory in just the past 50 years alone have enabled incredible advancements in many existing fields and have even enabled new fields (such as bioinformatics, social computing, eCommerce) by allowing data to be stored for later and widespread use.

Sources of Authority

The primary authorities in computational memories are archives of scientific reports (proceedings and journal articles, technical conferences) describing and analyzing them in the scientific literature. Such papers are rigorously studied, challenged, and cross-validated by peer experts, and ultimately replicated if they do hold advancements over existing solutions, before they are accepted as valid, implemented, and/or taught in a scholarly setting.

Ethical Principles

The general ethical principles are those standards in science. They include giving credit where it is due, respect for others' intellectual property, while advancing the well-being of individuals and society at large. Because advances by the discipline usually make possible actions by humans that were previously impossible (e.g., the accumulation of information about millions of people under the control of a few individuals in social website repositories or genomic databanks), it has been necessary to develop what some consider a unique type of ethics studies, so-called cyber-ethics (see ► [Cyberethics](#)). Many important ethical notions (such as privacy, intellectual property, digital identity, and legal regulations) are being transformed as a result.

Key Values

The key values are speed, reliability, capacity, data density, and meaningful results in memory systems.

Conceptualization

Nature/World

The world is the sum of data and the devices that store the data (sometimes called cyberspace, the Internet, the web, etc.).

Human Being

In the world of memories, human beings are actors that bring life and death to the world by creating data, consuming or interacting with data through using it applications, tools, appliances, instruments, etc., and destroying data by removing it from the world. In addition to flesh-and-blood homo sapiens, robots, household appliances, and software should also be considered "actors". The semantic web is a good example of a memory (world) where information is frequently created or destroyed by the flesh-and-blood actors in the form of news, web

content, music, pictures, etc., and stored in vast quantity for later intelligent retrieval with the expectation of reliable and human-relevant recall from the memory. Data is increasingly consumed by a wider variety of actors such as robots, household appliances, and special purpose. These machines are endowed with some degree of intelligence and are capable of assisting humans in performing tasks or substituting for humans for some tasks while maintaining similar results (e.g., IBM's *Watson* and *DeepBlue*). Deep Blue is a supercomputer constructed by IBM to play the game of chess by comparing the moves of the opponent, the current state of the game, and a very large memory, sufficiently well to compete with the best human chess players.

Life and Death

In the world of "memory", the life of data begins when the data is created or introduced into the memory and death occurs when it is removed from the memory. Although the concepts of life and death of data do not appear to be related to the ordinary meaning of the terms, data within a memory can represent a living person. Therefore, a tight interconnection may be assumed to exist between the referent of the data (e.g., a person) and its data. Therefore, the data may indicate that a person is not legal deceased until well after the person has physically expired. Further, the data about a deceased person can live well beyond the person.

Reality

The reality of a memory system amounts to the set of data stored and the information that can be retrieved from the memory. Reality, thus, excludes data that is actually stored but cannot be retrieved and data that is stored with errors. Consequently, "reality" is defined strictly by the accessible data whether true or complete. For example, cyberspace is an online memory in which an individual can assume a number of personalities, or can present himself to be a very different person than he or she is in the physical world by simply creating or altering data in the memory.

Knowledge

Knowledge is the new information that can be learned by studying or mining the data stored in a computer's memory. It may also refer to the technical knowledge necessary to build computational memory systems, including computational models, analyses, manufacturing protocols, and quality control.

Truth

Truth is the data actually stored inside the memory. Therefore, it may or may not be complete or correspond to any facts in the real world.

Perception

Data is often represented differently in memories than how humans consume it. Perception is, therefore, the conversion of information from how it is stored in memory to a consumable format. This perception (of a famous person, for example) may thus be quite different from that obtained by actual interaction with the reference (the actual person) in the data.

Time

Time is generally limited to the moment of creation, the last modification, or the time of deletion of the data within the memory. The measure of time is usually taken from a computer system's internal clock. This clock is digital (i.e., only records discrete time events) and may or may not be accurate enough to the human notion of time.

Consciousness

Computational memories do not usually appear to be capable of consciousness in the way humans do. However, some may argue that some computational memories may exhibit some characteristics of consciousness (e.g., when purchasing an airline ticket, the system may inquire about a car or a hotel reservation in the semantic web). Thus, the "consciousness" of a computational memory is probably best thought of as the means (programs and software) by which the memory decides what data is best to retrieve and in what order it should be retrieved. Alternatively, some in the field use the term "consciousness" as a

measure of quality in order to better understand the capabilities of some computational memories by comparison of the memories to human capabilities.

Rationality/Reason

Rationality is the "why" behind the retrieval choices of memory systems. Thus, rationality in a machine ordinarily reflects the rationality placed in the computer memories by its designers and programmers. However, new generations of computer memories might be regarded as becoming increasingly "rational" because of their advanced capabilities to combine data from disparate sources, mine the resulting memory to extract correlations and feasible conclusions, and present results which are frequently far from evident, or even credible, to rational humans confronted with the result.

Relevant Themes

The key issues for memories today are data encoding, semantic (human-like) retrieval of information from memory, memory structures that make processing easier, and density of storage. As mentioned before, it is conceivable that computational memories may be produced in the near future that exhibit features that closely resemble human memories, and even exceed their capability. IBM's *Watson* is a pioneering example.

Every modern computer is a binary system, and the very first computers were programmed directly in binary. However, binary is not intuitive for humans, and it can be very difficult and time consuming to write and debug. As a result, more abstract and human friendly computer languages were developed. The first of these languages was assembly, and it allowed a programmer to use character-based commands to program a computer. More languages were developed, and today a programmer has a wide array of languages to choose from. Each language has good and bad points, and it is up to the

Computer Science in Human Learning

Linda Sherrell

Department of Computer Science, The
University of Memphis, Memphis, TN, USA

Related Terms

Computer science; Computer science education

Description

Computer science (CS) education encompasses the teaching of computation from kindergarten through graduate school. To help prepare high school students who want to study computer science in college, many schools offer advanced placement (AP) courses in computer science. Students enrolled in these courses are then eligible to take corresponding exams offered by the Educational Testing Service (ETS). If their scores are high enough, universities may grant the students college credit for one or more courses. For example, the Computer Science A exam currently corresponds to a first-semester college course in object-oriented programming, where students learn problem-solving skills such as abstraction and ► [algorithm](#) development and are introduced to basic abstract data types. An abstract data type (ADT) is a built-in or userdefined type (kind of information) where the data has an associated collection of operations. Meanwhile, the Computer Science AB exam requires a knowledge of all the topics on the A exam plus a more advanced coverage of data structures (e.g., binary search trees, which require ► [recursion](#)). Although the AP College Board provides materials for computer science

courses, college enrollments in computer science saw drastic declines nationwide from 2002 through 2007. Even though this trend seems to be ending due to student interest in technology such as cell phones and iPods, the last year for the AB exam was in 2009.

Some of the recent changes in computer science education directly reflect declining enrollments. For example, because many middle- and high school students spend much of their leisure time playing computer games, several researchers developed curriculum materials targeting this interest. One of the most successful projects was the development of the software *Alice* (<http://www.alice.org>), which is offered freely by Carnegie Mellon University. *Alice*, which has been used in both high school and college settings, allows students to create 3D environments while learning ► [basic programming concepts](#). A more recent version called *Storytelling Alice* was designed especially for middle-school girls. Another notable tool for young students has been *AgentSheets* (<http://www.agentsheets.com>), which is best described as 2D game-authoring and simulation software. An interesting note about *AgentSheets* is that it has been used by middle-school students as well as NASA astronauts to build simulations. One of the most successful projects involving *AgentSheets* was Tri-P-LETS (Three P Learning Environment for Teachers and Students). In this project, funded by the National Science Foundation (NSF), the investigators and graduate students created curriculum modules to enhance the first- and second-year programming classes in public high schools in the Memphis area. A variety of simulations were assigned to students in order for the students to appreciate the breadth of the field and the types of courses that they would encounter if they selected CS as a major. For example, simulations were used to teach ► [combinatorics](#) (Sherrell et al. 2005), cellular automata (a theoretical computer where the world is represented as an infinite grid of cells. A cell has an associated state (alive or dead) and a set of rules associated with it), (Thomas et al. 2006), the hydrology life cycle, and DNA sequences. In addition, students followed an

adapted ► [waterfall model](#) with incremental coding and testing. Students were provided templates especially designed for *AgentSheets* projects in order to storyboard their simulation, record its requirements, document the logic, and track bugs (faults). Students were especially appreciative of the need for process when they designed large games and competed in the annual University of Memphis Programming Challenge, a competition where high school students work in teams for 6–7 weeks to develop an educational or adventure game.

There is an interesting, ongoing debate in computer science education concerning how one should teach the first programming course. In other words, should the instructor emphasize basic control structures and algorithm development or should he/she immediately introduce the concepts of a class and an object, which are required in object-oriented programming languages? The controversy reflects the two major pedagogical viewpoints known as objects-late versus objects-first. A popular objects-first approach appears in the textbooks authored by the creators of the interactive development environment BlueJ (<http://www.bluej.org>). However, some instructors prefer a declarative language (e.g., a functional programming language such as Scheme) or a scripting language as the first language.

Self-Identification

Science

This discipline/subdiscipline self-identifies itself as a science. Computer science educators make observations and collect data to better understand how students learn.

Characteristics

Computer science education differs from the other disciplines/subdisciplines in that it is relatively new. For example, the Association for Computing Machinery celebrated its 60th anniversary in 2007, and its associated journal

(*Communications of the ACM*) celebrated its 50th anniversary in 2008, whereas computer science education journals and associations are much younger.

Relevance to Science and Religion

For the majority of computer science educators, there is little interest in “science and religion.” However, for those teaching artificial intelligence, questions such as the following are of interest: How do mammals, insects, birds, and other members of the animal kingdom learn? Are there things about how animals learn that we can use to help us construct robots?

Sources of Authority

Conference and journal articles are the major sources of authority for this discipline/subdiscipline. The two most respected conferences for computer science education are sponsored by the Special Interest Group on Computer Science Education (SIGCSE) of the ACM. These conferences are *SIGCSE: Technical Symposium on Computer Science Education* and *ITiCSE: Innovations and Technology in Computer Science Education*.

Furthermore, the Computing Sciences Accreditation Board (CSAB) determines if existing undergraduate programs meet a set of standards. Even if CS departments do not seek accreditation, they may still refer to the CSAB standards to assess their programs. Another source of authority is *Computing Curricula*. The individuals who compose these guidelines for undergraduate programs are prominent individuals from industry and academia.

Ethical Principles

There are ten directives in the IEEE Code of Ethics (2006), whereas the ACM Code (1992) lists eight general imperatives. Those principles that are most similar are the following: Members

of these organizations should think of society and the public when making their decisions; be honest; not discriminate against people of other races, gender, disability, income, or age; and give credit to other individuals for their contributions.

Key Values

In both codes, specific professional responsibilities appear. By following these responsibilities, a member has accepted the values of the profession. An example value from the ACM Code is that members should strive to achieve the highest quality in their work. Note that the ACM Code lists eight professional values, six leadership values, and, finally, two imperatives that have to do with compliance to the code. Similar to the ACM imperatives, the last imperative of the IEEE Code states that members should support each other in following its established code of ethics.

Conceptualization

Nature/World

The nature of computer science education is to teach computational thinking (Wing 2006) to all human beings in the world.

Human Being

The discipline of computer science education considers a human being to be a member of the human race or, in other words, a person (living or dead). However, the discipline of artificial intelligence is interested in what determines a human being (see the answer to Question 4 above).

Life and Death

Life is the beginning of existence for members of the plant or animal kingdoms, whereas death is the ending of this existence. However, the discipline of software engineering considers the concept of life as the time that a software application is viable. In other words, the traditional software development “life” cycle begins with the vision

of a project through requirements, design, implementation, coding, postdelivery maintenance, and finally retirement (death). Testing and documentation are a part of each phase.

Reality

Reality refers to living or nonliving items that actually exist. Computer scientists are interested in “virtual reality” systems. These systems are simulations of imaginary worlds.

Knowledge

Knowledge is information gained through study and reasoning. This term appears in the names of two important subdisciplines of computer science education, namely, knowledge management and knowledge engineering.

Truth

Truth is a fact that has been proven or, in other words, the opposite of a falsehood. Computer science educators teach “truth” tables in the introductory computer science class to help students to reason logically.

Perception

Perception is an individual’s interpretation of a situation or a concept by the use of his/her senses. This term is also associated with the discipline of neural networks.

Time

Computer science educators define time in relation to the period measured in seconds, minutes, days, and so forth that an activity requires to be completed. They are especially interested in the “run-time” of various algorithms.

Consciousness

Consciousness is an awareness of a problem or concept. Artificial consciousness is a subdiscipline of artificial intelligence.

Rationality/Reason

Rationality is the ability to make a decision, whereas reason is the action of considering alternatives. Rationality is related to logic.

Mystery

Mystery is an occurrence or phenomenon with no logical explanation.

Relevant Themes

The IEEE Computer Society and the Association for Computing Machinery sponsored an interim report in December 2008 to the *Computing Curricula Report* of 2001. The 14 knowledge areas are still Discrete Structures, Human-Computer Interaction, Programming Fundamentals, Graphics and Visual Computing, Algorithms and Complexity, Intelligent Systems, Architecture and Organization, Information Management, Operating Systems, Social and Professional Issues, Net-Centric Computing, Software Engineering, Programming Languages, and Computational Science. Feedback from industry included the need for an increased emphasis in security, quality issues, software engineering principles and techniques, and the reengineering of large, undocumented code (ACM 2008).

Concept of God in Contemporary Philosophy of Religion

Karin Johannesson
Department of Theology, Uppsala University,
Uppsala, Sweden

According to some definitions, the phenomenon of ► religion is characterized by the belief that

there is a God or several gods. Belief in the existence of God or gods is, according to such definitions, the distinctive feature of religion. Such definitions underline the importance of the concept of God within the phenomena that we call religions. The concept of God plays a central role – perhaps *the* central role – within a religious tradition. Therefore, philosophers of religion take an interest in analyzing the concept of God and its use in different religious traditions.

What one understands to be a philosophical problem in relation to the concept of God partly depends on what philosophical tradition one belongs to. Philosophical reflection on the concept of God, engaged in by contemporary philosophers of religion, can be described in relation to the various philosophical traditions that influence this work since those traditions impact on the formulation of philosophical problems relating to the concept of God as well as on the philosophical analysis of them. Philosophers of religion working within different philosophical traditions discern different philosophical problems when reflecting on the concept of God and our different ways of using that concept. They do not always agree on what problems are genuine philosophical problems worth working on, nor do they always agree on what a fruitful approach to those problems might mean.

In this chapter, I will highlight the concept of God in contemporary philosophy of religion by focusing on how philosophers of religion within four different philosophical traditions use and analyze the concept of God in their philosophical work. The four philosophical traditions that I will focus on are discussed under the following headings: *Metaphysical Philosophy of Religion*, *Wittgensteinian Philosophy of Religion*, *Feminist Philosophy of Religion*, and *A Non-metaphysical Realist Approach to the Philosophy of Religion*. These four philosophical traditions are part of contemporary philosophy of religion relating to the analytical philosophical tradition. I choose to focus on the analytical tradition since it is normally in relation to this tradition that philosophical questions concerning religions and the sciences are posed and treated. Personally, I recommend the non-metaphysical realist

approach since this approach takes advantage of insights reached within the other three traditions as well as recent developments within the philosophy of science. However, many philosophers of religion still prefer to work within the tradition of metaphysical philosophy of religion.

Metaphysical Philosophy of Religion

According to *Filosoflexikonet*, an often-used Swedish dictionary of philosophical terminology, the term “metaphysical philosophy of religion” can denote the traditional form of philosophy of religion that devotes itself to a philosophical investigation into questions touching upon the existence and properties of God. Metaphysical philosophy of religion can relate to religion in a positive way or it can facilitate a critical evaluation of religion and religious belief in general (*Filosoflexikonet* 1988, p. 468).

When Philip Quinn defines philosophy of religion in *The Cambridge Dictionary of Philosophy*, he defines it as metaphysical philosophy of religion. Quinn writes that philosophy of religion is the subfield of philosophy devoted to the study of religious truth claims, primarily the most important of these claims, namely, the truth claims of the theistic traditions that concern the existence, nature, and activities of God. Quinn states that the focal point in philosophy of religion is what has been described by philosophers as the theistic concept of God. It is the coherence of this concept and the possible existence of an entity denoted by this concept that interests the philosopher of religion, he argues (Quinn 1995, p. 607).

Metaphysical philosophers of religion develop and analyze different arguments for or against God’s existence. These arguments almost exclusively concern the theistic traditions. It is mainly God as God is understood within Christianity, Judaism, and Islam that is of interest to the metaphysical philosopher of religion. Within these theistic traditions, God is, according to the metaphysical philosopher of religion, understood in a similar way. Within the theistic traditions, God is understood to possess certain great-making properties such as omnipotence,

omniscience, perfect goodness, and necessary existence. It is the task of the metaphysical philosopher of religion to investigate whether or not such a being may be believed to exist by analyzing arguments for or against God's existence.

Some metaphysical philosophers of religion are atheists. They maintain that there is no God and argue for this position. Other metaphysical philosophers of religion are believers belonging to some religious tradition, in most cases the Christian tradition. They argue for the existence of the God they believe in. Metaphysical philosophers of religion often relate to scientific research results when they argue for or against God's existence. For example, they may reflect on whether Darwinian evolutionary theory is incompatible with the belief in a creator God or if quantum mechanics can be used in order to show that it is likely that there is a creator God behind the Big Bang.

Metaphysical philosophers of religion understand the concept of God as referring to an object or entity that, if God exists, exists independently of us human beings in our common reality. Both sciences and religions make truth claims about the same reality, our common reality, according to the metaphysical philosopher of religion. This means that religious truth claims cannot be true unless they cohere with scientific truth claims known to be true. Therefore, one important task for the metaphysical philosopher of religion is to investigate whether religious truth claims made within a certain religious tradition can be said to be in accordance with present-day scientific research results.

One influential metaphysical philosopher of religion is Richard Swinburne (born in 1934). He explains the interest that the metaphysical philosopher of religion takes in the concept of God by stating that by "God" a theist understands something like a bodiless person who is eternal, free, all-powerful, all-knowing, perfectly good, the proper object of human worship and obedience, and the creator and sustainer of the universe (Swinburne 1993, p. 1). The metaphysical philosopher of religion investigates whether or not this understanding of God is coherent. Her interest in the coherence of the theistic concept of God is

related to her interest in questions concerning God's existence and nature. The metaphysical philosopher of religion maintains that if the theistic concept of God is not coherent, we know at least that a being such as the God described by the theist cannot exist. Either such a God does not exist or if God exists, God does not have all the properties ascribed to God by the theist.

This understanding of God's existence characterizes the interest that the metaphysical philosopher of religion takes in the coherence of the concept of God and in the possibility of arguing for or against God's existence by using present-day scientific research results. It also characterizes the approach that the metaphysical philosopher of religion takes to religious pluralism. If two different truth claims concerning God, made within two different religious traditions, disagree with each other, the metaphysical philosopher of religion concludes that both truth claims cannot be true. At least one of them has to be false.

This approach to religious pluralism suggests that questions concerning what religious tradition contains the correct truth claims will be in the foreground. The Christian God is described as the only God and as Trinitarian. This means, according to the metaphysical philosopher of religion, that if the Christian God exists, the Hindu goddess Kali cannot exist and the Muslim understanding of God as non-Trinitarian must be wrong.

The way in which the metaphysical philosopher of religion understands God's existence characterizes her understanding of and her work on the concept of God. Her understanding of God's existence can be described in relation to the ongoing debates on ► [realism](#) in the field. Metaphysical philosophy of religion often presupposes the philosophical position that Hilary Putnam names metaphysical realism, a position that I will return to when describing the non-metaphysical realist approach to the philosophy of religion.

Putnam describes metaphysical realism as comprising three central theses (Putnam 1981, p. 49). Firstly, the metaphysical realist presupposes that reality consists of some fixed totality of

mind-independent objects that constitutes reality-in-itself. She believes that there may be objects or states of affairs in reality-in-itself which we cannot experience or describe. Secondly, the metaphysical realist presupposes that we might imagine there to be only one true and complete description of reality. This is so because the metaphysical realist believes in a God's-eye point of view, an externalist perspective in relation to us humans and to our possibilities of experiencing, knowing, or stating what things are really like in reality-in-itself. Thirdly, the metaphysical realist thinks that we speak the truth insofar as our utterances correspond in some way to the states of affairs in reality-in-itself. Different metaphysical realists describe this correspondence in different ways, but what they all agree on is that it is entirely possible that we do not know, and cannot know, that a true utterance is in fact true. "The most important consequence of metaphysical realism," Putnam summarizes, "is that *truth* is supposed to be *radically non-epistemic*" (Putnam 1978, p. 125). The metaphysical realist presupposes that what is true is independent of our abilities to find out whether it is true. What is true is not, according to the metaphysical realist, determined by us, from an internal linguistic perspective, but rather by reality-in-itself, from an external perspective.

This metaphysical realist position is questioned by philosophers of religion working within philosophical traditions other than metaphysical philosophy of religion. I will, in turn, describe three such alternative traditions. Two of them are influential within contemporary philosophy of religion, and the third one is my own preferred approach.

Wittgensteinian Philosophy of Religion

Wittgensteinian philosophy of religion is inspired by Ludwig Wittgenstein's later philosophy. Wittgensteinian philosophers of religion believe that metaphysical philosophy of religion is an expression of a huge misunderstanding. Religious language and religious truth claims do not

work in the ways that the metaphysical philosopher of religion assumes that they work. Wittgensteinian philosophers of religion want to set us free from the misunderstandings on which they believe metaphysical philosophy of religion to be built. In doing so, they set a different philosophical agenda.

When John Hyman describes Wittgensteinianism in *A Companion to Philosophy of Religion*, he emphasizes that the philosophy of the later Wittgenstein is centered on the insight that the meaning of a word is its use in the language. Words can be used for an indefinitely broad and heterogeneous range of purposes. The task of philosophy is not, according to the later Wittgenstein, logical analysis but the description of what Wittgenstein names different *language games*. Since speech and writing are part and parcel of human activities which take place and have significance only in the context of what Wittgenstein names different *forms of life*, the question of what an expression in a language means can only be answered by considering it in its context and by asking how it is used. The philosopher's task is to describe our network of concepts, what Wittgenstein calls *grammar*, in order to free us from the misunderstandings concerning the use of our words that give rise to confusion and philosophical problems. The philosopher should remind us of what we already know by knowing the use of our language: the proper use of our words according to the grammar which rules the language game in question in a certain form of life (Hyman 1997, pp.153–156).

Wittgensteinian philosophers of religion describe the grammar ruling different language games in contexts that we understand as religious contexts, as religious forms of life. What this means is not obvious; therefore, Wittgensteinian philosophers of religion also have to explain and defend their Wittgensteinian approach. How do we draw the line between one form of life or one language game and another? Is Hindu faith one form of life or several forms of life? Can Christian prayer be understood as a language game or should we understand Christian thanksgiving as one language game and Christian

prayers for forgiveness as another language game? The answer that Wittgensteinian philosophers of religion tend to give to this kind of question is that how we draw the line depends on what confusion the philosopher tries to free us from. Sometimes we can do away with our confusion by understanding Christian prayer as a language game, and sometimes we understand Christian thanksgiving as one language game and Christian prayers for forgiveness as another language game.

One prominent Wittgensteinian philosopher of religion is D.Z. Phillips (1934–2006). He argues that metaphysical philosophy of religion is built on conceptual confusions. These misunderstandings give rise to metaphysics. They make us draw the mistaken conclusion that religious faith is a theory involving the thesis that there exists an entity that we name “God” or several entities that we name “gods” and that it is the philosopher’s task to argue for or against this theory or this thesis. Religious faith is not a theory, according to Phillips, and it is not the philosopher’s task to argue for or against the metaphysical claims that the metaphysical philosopher of religion circles around. Instead, Phillips argues, it is the philosopher’s task to free us from the conceptual confusions that give rise to metaphysical philosophy of religion (Cf. Phillips 1988, pp. 195, 201, 209, 308).

Phillips underlines that the philosopher’s aim is not to persuade people to believe but to understand the character of their beliefs. The philosopher, it might be said, is the guardian of grammar. The theologian, by contrast, is the guardian of faith, the one interested in defending his or her faith in order to gain new followers. The difficulty that Wittgenstein’s work presents to the metaphysical philosopher of religion is that it stands outside the apologetic context. This might be difficult to appreciate if philosophy itself is conceived of as a way to assess religious belief *pro* and *contra* (Phillips 1988, pp. xvi–xvii, 113, 238).

In philosophy, we are not testing theories, according to the Wittgensteinian philosopher of religion, but struggling with confusions. Some of

these confusions concern our use of the concept of God. We tend, as the metaphysical philosopher of religion, to understand the concept of God as a concept referring to an object or an entity that we may or may not believe exists in a reality independent of us. To avoid this confusion, we must look to the forms of life in which talk of God has a role to see what application the notion of the independently real has there. This means that instead of asking how or if we can speak of God, we must begin by noting that we do speak of God (Phillips 1988, p. 264). There are many religious forms of life and religious language games within which people do speak of God. It is the philosopher’s task to describe the grammar ruling the use of the concept of God within these contexts.

Philosophers criticizing the Wittgensteinian philosophers of religion present them with the following choice: either the word “God” refers to an object or it is a metaphorical use of language. The Wittgensteinian philosophers of religion deny that the word “God” refers to an object. They also deny that the word “God” is a metaphorical use of language. They reject this simple choice. This is because they believe that no one account of what “agreement with reality” amounts to can be given since the meaning of what agreement with reality comes to is itself determined by the language games we play and the forms of life they enter into (Phillips 1988, pp. 55, 206, 317).

Phillips argues that by studying the grammar ruling the use of the concept of God, we will come to understand that the God in whom religious believers believe is one of whom it makes no sense to say that he may or may not exist. The dispute between belief and unbelief is, according to Phillips, not one in which evidence and probabilities are weighed within a common system. Instead, the gap between what the believer wants to say and what the unbeliever denies is a grammatical gap. To reject religion, or to come to God, is not to reject or embrace a hypothesis within a common way of looking at things but, rather, to reject or embrace a whole way of looking at things. Within the religious way of looking at things, it is not meaningful, according to Phillips, to say either that God may

exist or that God may not exist. Within the religious way of looking at things, God is not an object or entity that may or may not exist. If, per impossible, any object were said to correspond to the word “God,” one thing would be certain: that object would not be God (Phillips 1988, pp. 11–12, 80, 321).

Wittgensteinian philosophy of religion stresses the difference between religious belief and science. Religious faith and scientific hypotheses belong to different forms of life, and it is important not to confuse or blend language games from these different contexts with each other. If, for example, the religious believer or scientist tries to argue for or against God’s existence by using scientific results, a conceptual confusion is at hand. It is the philosopher’s task to deliver us from this conceptual confusion by reminding us that the grammar ruling our use of the concept of God states that belief in God is not a scientific hypothesis that we may argue for or against. To understand religious faith in such a way is to misunderstand it, according to the Wittgensteinian philosopher of religion.

When it comes to religious pluralism, the Wittgensteinian philosopher of religion emphasizes that in asking whether or not believers within different religious contexts mean the same when using the concept of God, we can get confused by thinking that speaking about God has anything in common with referring to the same object. The philosopher should not treat religious pluralism as a question concerning which religious theory, if any, might be the correct one. Instead, the philosopher of religion should describe the grammar ruling different language games within different religious contexts without judging those language games and without suggesting how they may be adjusted in order to accord with some other language game within another religious context. This means, among other things, that it is not the philosopher’s task to help religious people belonging to different religious contexts to come to an agreement concerning what core beliefs they ought to accept but to help them understand the character of their own beliefs as well as that of others.

Feminist Philosophy of Religion

When Grace Jantzen describes ► [feminist philosophy of religion](#) in *Companion Encyclopedia of Theology*, she stresses that feminist philosophers of religion pay attention to the fact that God, as God is described within the theistic traditions, is very often understood to be a male person since the properties ascribed to God often is understood as “masculinist” (Coakley 1997, pp. 601–606). Also, believers tend to refer to God by using male personal pronouns. When philosophers of religion summarize the most important properties that, according to them, are incorporated within the theistic concept of God, their lists very seldom include the property of being male even though philosophers of religion also tend to refer to God by using male personal pronouns. Is the use of male pronouns just an innocent linguistic practice with no severe consequences or is it the tip of an iceberg that ought to attract our attention not only to the male personal pronouns used when referring to God but to the whole cluster of properties incorporated in the theistic concept of God?

Feminist philosophers of religion maintain that not only the use of male personal pronouns when referring to God but the whole theistic concept of God ought to be analyzed from a feminist philosophical perspective. The great-making properties that philosophers of religion summarize in their lists describing the theistic concept of God often include properties that we associate with male gender. Being powerful and all-knowing are properties that dominating males who suppress women find valuable and therefore ascribe to God. Likewise, being without a body and being detached from the world are usually understood to be properties of the male gender, while women are traditionally thought to be corporeal and to have feelings of attachment. Feminist philosophers of religion therefore argue that the whole theistic concept of God that dominates influential religious traditions as well as mainstream philosophy of religion must be investigated from a feminist philosophical perspective. The detached interest in the logical coherence of

the theistic concept of God, characteristic of metaphysical philosophy of religion, must be questioned in the light of the more pressing issues concerning the oppressive consequences of this concept.

In her work on feminist philosophy of religion, Pamela Sue Anderson takes an interest in epistemological questions (Anderson 1988). In doing so, she poses the question: *Whose* philosophy is the philosophy of religion? Within the philosophy of religion, what feminists call the “generic male” (i.e., the privileged male subject posing as a sexless individual of universal instantiation) has become the norm (Coakley 1997, p. 601). This, they argue, characterizes the problems that philosophers of religion formulate and choose to work on, the strategies they understand to be acceptable within a philosophical discipline and the solutions that they recommend. The ideal reflecting, arguing, and knowing subject that produces sound philosophy of religion is a male subject.

By taking an interest in epistemological questions, feminist philosophers of religion draw attention to interrelations between our descriptions of the way the world is, our values, and our standpoint in the world. The fact that philosophy of religion is usually approached from a male perspective, a perspective that highly values what we humans understand to be male properties, inevitably affects the description of the world that the philosopher of religion presupposes in posing his problems and arguing for his solutions. There is no neutral description of the world, the feminist philosopher of religion argues. There is no God’s-eye point of view that we can strive for or imagine. We human beings are always situated in time and space. When we describe the world, we do so from some perspective. As human beings, we live on earth by having a certain body, located within a specific context, with certain values and certain linguistic assets. Our standpoint characterizes the description of the world that we formulate. Our description of the world, in turn, has consequences for how we live our lives and how we treat each other. We have to evaluate our descriptions of the world in

relation to our values in order to avoid descriptions of the world which are formulated by oppressors and which lead to further oppression.

This emphasis on the interrelation between our descriptions of the world, our values, and our standpoint in the world is something that the feminist philosopher of religion shares with the philosopher of religion who chooses a non-metaphysical realist approach.

A Non-metaphysical Realist Approach to the Philosophy of Religion

The philosopher of religion who chooses a non-metaphysical realist approach concurs with present-day philosophy of science in assuming that we can state things only if what we say is related to some idea about the circumstances under which we would be able, as human beings, to justify that statement. It must be possible for other people to discern this idea by studying the linguistic behavior in the speech community to which we as speakers belong. This does not mean that the individual speaker must be able to formulate an opinion about the circumstances under which we would be able to justify her statement. It is the philosophical observer of the speech behavior in the speech community that must be able to do that. Nor does it mean that, at present, we humans can actually, in practice, justify the statement in question. Perhaps only some future expert will be able to do that. However, it does mean that sentences cannot be statements unless they are connected to some idea about the circumstances under which we would be able to justify the sentence in question. For example, the metaphysical realist belief that there exists a reality-in-itself cannot be stated because we cannot per definition justify the existence of such a reality. If the existence of a reality-in-itself could be confirmed by us humans, it would not be a reality-in-itself. It would be a reality understood from a human perspective, a reality described by humans using certain linguistic devices and shown to exist by human beings presupposing certain

epistemological values. This means that, according to the philosopher of religion who chooses a non-metaphysical realist approach, the metaphysical realism that is presupposed within metaphysical philosophy of religion is a philosophically untenable position (Johannesson 2007, p. 245).

By assuming that the only utterances that can be statements are utterances related to some idea concerning sufficiently good conditions for justification, we can conclude that we humans are able to interpret all speech behavior that can be considered human language. This is so because it will always be possible to discern the ideas concerning justification that give our statements their content by studying the linguistic behavior within a speech community. When we know under what circumstances a speaker would make a certain statement, we can interpret that statement by stating its content using our own conceptual resources. The fact that different human speech communities using different conceptual resources will be inter-interpretable gives rise to a non-metaphysical realist position. Non-metaphysical realism is a philosophically tenable point of departure for the philosophy of religion. What this means can be explained by returning to Putnam and the three theses he ascribes to the metaphysical realist.

It is possible for us to understand all three theses attributed to the metaphysical realist in a non-metaphysical realist way. The world can be conceived of as consisting of that totality of mind-independent objects which we, with the help of our conceptual resources, can rightly state exists. The fact that we can rightly state that a specific object exists could mean that we think that, given sufficiently good conditions for the justification of such a statement, we would claim that this statement is an expression of correct linguistic behavior. This means that we conceive of this statement as true, as corresponding to reality. The one and only true description of reality could consist of all the statements about what does or does not exist which we would conceive of as corresponding to reality if sufficiently good conditions for justifying each statement were realized (Johannesson 2007, pp. 232–233).

This non-metaphysical realist reinterpretation of the three theses does not regard reality as a reality-in-itself but rather as a reality that relates to what we humans can state, what we can experience, and what we consider to be sufficiently good conditions for justification. In this sense, it is a reality described, not from a God's-eye point of view but from a human-eyes point of view. Just as the feminist philosopher of religion, the philosopher of religion who chooses a non-metaphysical realist approach stresses the interdependence between our linguistic resources (that determine what statements we are able to formulate), our values (including the epistemological values that decide what we understand to be sufficiently good conditions for the justification of a certain statement), our standpoint in the world, and our descriptions of reality.

It should be emphasized that it is hardly likely that we humans will ever be in such complete agreement about what objects we can rightly state exist or what constitutes sufficiently good conditions for justification that we will be able to formulate the one and only true and complete description of reality. This description of reality, and its consequent delimitation of the totality of mind-independent objects, is a hypothetical notion; however, unlike the metaphysical realist conception of a reality-in-itself, it is a hypothetical notion that it is possible for us to understand since it refers to a reality with which we interact.

The fact that the metaphysical realist and the non-metaphysical realist embrace the same three theses should not lead us to ignore the differences between these two perspectives. One important difference is that the non-metaphysical realist, just like the Wittgensteinian philosopher of religion, will have to maintain that all philosophical reflection has to be done in connection to some existing speech community whose linguistic behavior the philosopher studies. This is so because if the philosopher of religion does not study the linguistic behavior of some existing speech community, she will not be able to state under what circumstances the statements that she focuses on could be considered justified, and

therefore, she will not be able to understand what they mean.

It is important to note that the philosopher of religion who chooses a non-metaphysical realist approach can work with the questions concerning God's existence that have become the trademark of metaphysical philosophy of religion even if this work will be done in a different way. Before starting to discuss whether or not God exists, the philosopher of religion who chooses a non-metaphysical realist approach must clarify the meaning of the claim that God exists or the claim that God does not exist by stating some idea about the circumstances under which we would be justified in making one of those statements. This idea about conditions for justification must be explained in relation to the linguistic behavior in some existing speech community. The fact that the philosopher of religion will have to treat questions concerning the concept of God or God's existence in relation to some actually existing speech community will have consequences for the philosophical agenda. Some of the questions traditionally treated in philosophy of religion are rarely triggered by existing speech communities outside the philosophical discourse. The philosopher of religion who chooses a non-metaphysical realist approach might therefore find that other questions than the ones traditionally treated in the philosophy of religion are more interesting to study simply because some existing and influential speech community gives rise to them. This might mean that philosophers of religion become more interested in non-Christian religious traditions which gain influence in present-day society. It may also mean that the relation between religions and the sciences is seen from a different angle than the one given by metaphysical philosophy of religion.

Description

According to the temperature of the system, matter can be found in three different states: gas, liquid, and solid. Gas is the state where the individual constituents are free to move. In liquid state, the constituents are bound and their motion is restricted. In the solid state of matter, the constituents occupy fixed positions. Solids can exist in the crystalline or amorphous form. In the *crystalline* form, the atoms or ions are arranged in a periodic array, i.e., there is a long-range order in the system. In the *amorphous form*, there is no long-range order.

Solid-State Crystals

Crystals are formed by the infinite regular repetition in space of identical building blocks. The elementary building blocks are atoms or groups of atoms. In the simplest crystals such as copper, gold, silver, and alkali metals, the structural unit consists of a single atom. More generally, the structural units consist of several atoms or molecules. The structure of all crystals is described in terms of single periodic lattice, with a group of atoms attached to each lattice point or situated in each elementary parallelepiped. This group of atoms is called the *basis*. The basis is repeated in space to form the crystal: crystal structure = lattice + basis. A typical example of a simple crystal structures is the structure of *sodium chloride* – NaCl. The fundamental type of its lattice is face-centered cubic; the basis consists of one Na atom and one Cl atom.

Ionic crystals are made of positive and negative ions – i.e., atoms having some excess or lack of electrons which makes them behave as electrically charged objects. The ions are kept together by the Coulomb attraction between ions of opposite sign stronger than the Coulomb repulsion between ions of the same sign. The *ionic bond* is resulting from the electrostatic interaction between ions of opposite sign. The NaCl structure is an example of an ionic crystal structure.

Covalent crystals are made of neutral atoms held together by the so-called covalent bond, electron pair, or homopolar bond. For example, in the molecule H₂, the hydrogen atoms share the two electrons via covalent bonding. The covalent bond is as strong as the ionic bond and has strong directional properties – its strength depends on the angular relation between the atoms in a molecule. The covalent bond is usually formed from two electrons – one from each atom participating in the bond. The two atoms can be from different chemical elements but should have comparable electronegativity – a chemical property describing the ability of an atom to attract electrons. The electronegativity of an atom depends on its atomic weight, and the distance forms its valence (most external) electrons that reside in relation to the positively charged nucleus. The higher is the electronegativity, the larger is the degree of attraction of the electrons toward the atom.

Crystals of inert gases. The inert gases form the simplest crystals. The crystals are transparent insulators and are weakly bound with low melting temperature. The outermost electronic shells of the atoms are completely filled. In the crystal, the inert gas atoms are packed together as closely as possible. The typical crystal structures are all cubic close-packed. The inert gas crystals are held together by *van der Waals-London interactions*. This interaction is due to the fact that the electrical charge distribution on the atom is not rigid. The electrons are in motion around the nucleus even in the lowest electronic state, and at any instant of time, there is a nonvanishing electric dipole moment from the motion. An instantaneous dipole moment of one atom produces an electric field at the center of the second

at some distance R of the first atom. The field will induce an instantaneous dipole moment on the second atom. These two dipole moments will interact. This interaction is known as the van der Waals interaction, London interaction, or induced dipole-dipole interaction. It is the principal attractive interaction in crystals of inert gases.

Metal crystals. The main characteristic of metal crystals is a high electrical conductivity. A large number of electrons in a metal are free to move around, usually one or two per atom. The electrons available to move about are called conduction electrons. In some metals, the interaction of the conduction electrons with the ion core makes a large contribution to the binding energy. Alkali metal crystals may be considered as an array of positive charges embedded in a sea of negative charges. In the transition metals, there may be additional binding from inner electron shells. Transition metals have large d-electron shells and are characterized by high binding energies, caused in part by covalent binding and in part by van der Waals interaction of the cores.

Hydrogen-bonded crystals. A hydrogen bond is formed when two nonhydrogen atoms attract a hydrogen atom. The hydrogen bond is rather ionic in character; being formed only between the most electronegative atoms F – fluorine, O – oxygen, and N – nitrogen.

Semiconductor Crystals

A semiconductor is neither a good insulator nor a very good conductor of electrical current.

Introduction

Composition of Semiconductors Some of the most important semiconductor elements are silicon and germanium which are part of group IV of the periodic table of elements. Various forms of carbon also can be semiconductors. Other elements with semiconductor properties are selenium and tellurium of group VI. The list of binary semiconductor compounds is very large. It includes the compounds formed from group III and group V elements, from group II and group IV elements, and from group IV and group VI elements. There are also many ternary and organic semiconductor compounds.

Electronic Energy Bands To understand the basic properties of semiconductors, it is necessary to refer to the quantum concept of energy bands. For the free atoms, the energy levels are single quantum (or discrete) states. When the atoms are brought together in a crystal, the quantum rules do not allow for the atomic energy levels of the individual atoms to overlap and coincide. Thus, the individual atomic energy levels degenerate and form energy bands. In a periodic lattice of a crystal, the electrons move freely as if the ions are instantaneously at rest. The eigenstates of an electron moving in the periodic potential of a crystal are the so-called Bloch states. The energy of the Bloch states cannot take all possible values but are restricted to certain allowed regions or bands separated from one another by forbidden regions or band gaps.

In a pure semiconductor without defects and at the absolute temperature scale zero, 0 K, certain bands are completely full of electrons and the remaining bands are completely empty. This situation corresponds to an insulator. If the temperature of the crystal is raised, electrons will be excited from filled bands to empty bands, leading to partial occupancy of these bands. Under these conditions, the crystal becomes a semiconductor with a conductivity which increases rapidly with increasing temperature as more and more electrons are excited in the empty bands.

There is a gap between the top edge of the highest filled band and the bottom edge of the lowest empty band. This gap is called fundamental gap. The electrons in the highest filled bands are valence electrons, and the bands they occupy are the valence bands. The bands that are empty at 0 K are conduction bands. When an electron is promoted from the valence band to the conduction band, it becomes a conduction electron. The lack of the electron in the valence band is called hole. The holes which are left in the valence band are positively charged. Therefore, electrons in the conduction band are negative electric charge carriers and the holes in the valence band are positive charge carriers.

Amorphous Semiconductors In amorphous semiconductors, the atoms do not form

a periodic array, but are disordered. Nevertheless, a sufficient short-range order remains so that the electronic energy properties retain their basic features. Band edges however are smeared out, and band gaps are no longer clearly defined. States which are moved into what had been the forbidden gap may now have a distinctively localized character. Amorphous semiconductor alloys are frequently used in applications. In particular, amorphous Si-Ge alloys are useful in solar cells in view of the possibility to maximize performance by varying the composition.

α -Si:H (hydrogenated amorphous silicon) is one of the most common amorphous semiconductors. A silicon lattice is tetrahedrally bonded (a tetrahedron is a geometrical figure composed of four triangular faces, three of which meet at each of its four vertices). Creating disorder in the silicon lattice causes relaxation of the requirement for fourfold coordination of the nearest neighbors and produces the so-called dangling bonds – a type of bond that occurs when an atom is missing a neighbor to which it would be able to bind. These bonds need to be saturated and combine easily with monovalent atoms such as H to yield α -Si:H.

Impurity Effects Introduction of impurities in a semiconductor may have drastic effects on its properties and, in particular, on its electronic properties. Impurities can provide additional carriers such as conduction electrons or valence holes, and scattering centers, which perturbs the motion of the freely moving carriers.

If a group V element such as P is added to a group IV semiconductor like Si, it may enter substitutionally into the crystal by replacing Si atoms in the silicon diamond structure. Phosphorus contains five electrons behind closed shells of which four can be paired up with electrons on four neighboring Si atoms to form four electron-pair bonds. The fifth electron is bound to the P⁺ ion at sufficiently low temperature, but is thermally excited to the conduction band at higher temperatures and contributes to the conductivity. Phosphorous is called donor impurity because it donates electrons to the conduction band.

Silicon doped with P is known as n-type Si because the electric current carriers provided by P are negatively charged electrons in the conduction band.

Let us now consider an impurity from group III of the periodic table such as boron (B), which can also enter Si substitutionally. Boron contains three electrons behind closed shells and therefore lacks one electron needed to form electron-pair bonds with the nearest neighboring Si atoms. The missing electron on the B atom can be regarded as a hole. At sufficient low temperature, the hole bounds to the B atom. At high temperature, one electron from a far away electron-pair bond can transfer to the B atom and, together with the other three electrons, form four electron-pair bonds between the B atom and the four nearest neighbor Si atoms. The hole is thereby transferred from the B atom to the far away electron-pair bonds and is no longer bound to the B atom. The B atom in this process has become negatively charged. Boron is referred to as an acceptor impurity because it accepts electrons from elsewhere in the crystal. Si doped with B is known as p-type Si because the electric current carriers provided by B are positively charged holes.

Impurity Bands Impurity effects can be created and controlled by doping semiconductor crystals with appropriate foreign atoms in a way similar to the one that was described above. Such impurities or dopants introduce newly allowed electronic energy levels within the band gap. These energy levels are close to the conduction band for n-type and close to the valance band for the p-type semiconductors. At sufficiently high concentration, neighboring atoms are sufficiently close to produce sufficient perturbation of the impurity levels. The energy levels broaden out into a band called impurity band.

Lattice Vibrations An important source of deviation from the periodicity in a crystal is the displacement of an atom from its equilibrium position. These deviations arise naturally from the thermal energy of the atom. If the crystal is in a stable configuration, the displacement of an

atom leads to a force that tends to restore the atom to its equilibrium position. However, the kinetic energy of the atom causes it to overshoot the latter. As a result, the atom vibrates about its equilibrium position. The forces of interaction between atoms couple the atomic vibration together, giving rise to lattice vibrations. When an atom of the pure crystal is substitutionally replaced by an impurity atom, the mass of the atom and the force constants coupling it to its neighbors are changed and a localized vibrational mode arises in which the amplitude of vibration is large at the impurity site and decreases exponentially going away from the site.

Semiconductor Properties

Electrical Properties The electrical resistivity of semiconductors generally decreases strongly with increasing temperature, whereas the resistivity of a metal generally increases weakly with increasing temperature. In fact, solid materials are usually classified into three categories based on their electrical resistivity: insulators when the resistivity is very high, metals when the resistivity is very low, and semiconductors for which the resistivity is intermediate and is highly dependent on the temperature. The temperature dependences of the resistivities of metals and semiconductors are quite different. For metals, the temperature dependence is rather weak and the resistivity increases with increasing temperature. For semiconductors, the opposite is typically the case. The temperature dependence is rather strong, and the resistivity decreases with increasing temperature.

Dielectric Properties Certain crystals exhibit a dipole moment in the presence of an electric field E . The polarization P in such crystals is defined as the dipole moment per unit volume of a crystal cell. The dielectric susceptibility of an isotropic or cubic medium is defined as $\chi = P/E$.

Piezoelectric Effects Some crystals have the property that if the crystal is strained, an electric dipole moment and an associated electric field develop. This phenomenon is called

piezoelectricity and can be explained by the compositional asymmetry of the basic structural elements of the crystals (only crystals without center of inversion can exhibit it). The semiconductors of the zinc blende structure, such as GaAs, and of the wurtzite structure, such as CdS, exhibit piezoelectricity.

Ferroelectricity A ferroelectric crystal exhibits an electric dipole moment even in the absence of an external electric field. In the ferroelectric state, the center of the positive charge of the crystal does not coincide with the center of negative charge. The variation of polarization as a function of the electric field for the ferroelectric state represents a typical loop called hysteresis loop. The crystal in a normal dielectric state usually does not show a perceptible hysteresis when the electric field is increased and reversed slowly. Ferroelectricity usually disappears above a certain temperature called transition temperature, and above the transition, the crystal is said to be in a paraelectric state.

The ferroelectric crystals are said to be of *order-disorder* type when the transition is associated with the ordering of ions, or of *displacive* type when the transition is associated with the displacement of a whole sublattice of ions of one type relative to another sublattice. All crystals in a ferroelectric state are also piezoelectric. A stress applied to the crystal will change the electric polarization, and similarly, an electric field applied to the crystal will cause the crystal to be strained.

Transport Properties Transport properties such as electrical conductivity play a critical role in the application of semiconductors to electronic devices. A system of free carriers in an energy band can be considered as a gas of noninteracting charged particles. When an external force is applied, the carriers are displaced under the influence of the field and an electrical current results. The external force may be due to an electric field producing electric conduction current, to a concentration gradient giving rise to diffusion current, or to a thermal gradient leading to a heat

current associated with thermal conductivity. In the absence of an external force, the charge carriers execute the random Brownian motion resulting from collisions due to the interaction of carriers with impurities, lattice vibrations, and other perturbations of the periodic potential. During collision, the carrier may undergo a sharp change in direction, but between collisions, its motion is essentially rectilinear and characterized by its mean free speed.

Magnetic Properties The magnetic moment of a free atom has three principal sources: the spin with which electrons are endowed, their orbital angular momentum, and the change in orbital momentum induced by the applied magnetic field. The magnetization M of a semiconductor material is defined as the magnetic moment per unit volume. The magnetic susceptibility per unit volume is defined as $\chi = M/B$, where B is the macroscopic magnetic field intensity. Substances with a negative magnetic susceptibility are called diamagnetic. Substances with a positive susceptibility are called paramagnetic. A positive contribution to χ can be found in lattice defects possessing an odd number of electrons, as the total spin of the system cannot be zero. Electronic paramagnetism is found also in metals and in free atoms and ions with partly filled inner shell. A ferromagnet has a spontaneous magnetic moment even at zero applied magnetic field. A spontaneous moment means that electron spins and magnetic moments are arranged in a regular manner. The temperature above which the spontaneous magnetization vanishes is called the Curie temperature T_c . The Curie temperature separates the disordered paramagnetic phase (at $T > T_c$) from the ordered ferromagnetic phase (at $T < T_c$). At temperatures below the Curie point, the electronic magnetic moments of a ferromagnet are all lined up when regarded on a microscopic scale. Yet, looking at a specimen as a whole, the magnetic moment may be much less than the saturation moment. To explain this behavior, Weiss assumed that actual specimens are composed by a number of small regions called domains, within each of which the local magnetization is saturated. The transition layer

which separates domains magnetized in different directions is called a Bloch wall.

Compounds in which some ions have a moment antiparallel to other ions are considered as ferrimagnetic. Many ferrimagnets are poor conductors of electricity, a quality which is exploited in device applications. There exists also an antiferromagnet order in which the spins in a single plane are parallel, but adjacent planes are antiparallel. In an antiferromagnet, the spins are ordered in antiparallel arrangement with zero net moment at temperatures below the so-called Néel temperature T_N . An antiferromagnet is a special case of ferrimagnet for which both sublattices have equal saturation magnetization.

Superconductivity The electrical resistivity of many solid materials, metals and alloys, and some particular compounds drops suddenly to zero when the specimen is cooled to sufficiently low temperature. At a critical temperature T_c , the specimen undergoes a phase transition from a state of normal electrical resistivity to a superconducting state.

The magnetic properties exhibited by a superconductor are as dramatic as their electrical properties. When a specimen is placed in a magnetic field and cooled through the transition temperature for superconductivity, the magnetic flux usually present is ejected from the specimen. This is called the Meissner effect.

Optical Properties of Semiconductors The optical properties of matter are associated with the absorption, dispersion, and scattering of electromagnetic radiation. All these processes are relatively complex optical phenomena when considered within the context of condensed matter physics and in semiconductor physics in particular. The nature of optical absorption and scattering could be somewhat intuitively understood. However, this is not so with dispersion which describes optical material effects associated with the fact that in a semiconductor (the same as in any other type of material), the different spectral components of an optical pulse propagate with different speeds. The absorption, dispersion, and scattering of electromagnetic

radiation arise as a result of the perturbation of the material system by the electromagnetic field. The perturbation can involve the electronic state or the vibrational state or both and leads to transitions between the states. The phenomena produced by this perturbation include infrared intrinsic interband absorption, free carrier absorption, lattice vibration absorption, Raman scattering, and electron Raman scattering. Light absorption leads to photoconductivity with applications as photodetectors and photovoltaic effect as solar cells.

In the process of *optical absorption*, light is absorbed by crystals to create electron-hole pairs. When the energy of the absorbed photon is close to the energy gap, but just below, the electron-hole pairs remain bound by Coulomb interaction. This initial bound state is called *exciton*; it may move through the crystal transporting excitation energy but not charge. Interacting with phonons or impurities, the exciton may be dissociated, giving free electrons and holes. For photons with energies greater than the energy gap, electrons from the valence band are excited directly into the conduction band, giving free electrons and holes which may move independently.

Photoconductivity is another phenomenon which is related to both the optical and the electrical properties of semiconductors. In general, it is associated with the increase of the electrical conductivity of an insulating crystal caused by radiation incident on the crystal. The direct effect of light illumination is to increase the number of mobile charge carriers in the crystal, giving rise to the manifestation of electrical current phenomena.

The color presented by a crystal is usually the color of light transmitted through the crystal. A perfect diamond is clear because there is no light absorption in the crystal. Cadmium sulfide with an energy gap of 2.42 eV absorbs the blue region of the spectrum and is therefore yellow orange. Silicon has a metallic luster because the band gap of 1.14 eV is below the visible region of energy. Ruby is a dark-red gem; sapphire is a blue gem. Both are impure crystals of Al_2O_3 which is colorless when pure. The color of ruby is caused

by Cr^{3+} impurities. The blue color of sapphire is due to Ti^{3+} ions present as impurity in Al_2O_3 .

Semiconductor Structures and Lasers

P-N Junction in Semiconductors The p-n junction represents the interface between two regions, one of which is p type and the other n type. On both sides of the interface, electrons and holes diffuse and recombine, leaving uncompensated charged ions that constitute a space charge region or depletion layer. From the region of positive ions on the n-type side toward the region of negative ions on the p-type side exists a built-in electric field. The charge density is positive on the n-type side and negative on the p-type side. The simplest semiconductor device is the p-n junction which is used as rectifier. It also serves as the basis of the transistor which has important applications as amplifier.

Heterostructures A heterostructure consists of two different semiconductors in intimate contact. A heterojunction is a heterostructure with semiconductors of different types. A modulation-doped heterostructure involves two semiconductors, one highly doped on one side and one intrinsic on the other side of the interface. A very thin layer of conduction electrons can be created which constitutes a two-dimensional electron gas (2DEG). The electron energies in a 2DEG form electronic subbands which arise from the confinement of the electrons in the direction normal to the junction interface.

A square-quantum well is formed by placing a thin layer of small-gap semiconductor between two thick layers of large-gap semiconductor. Coupling together larger and larger number of quantum wells leads to the creation of a superlattice with an allowed band of energy levels.

Semiconductor Lasers Crystals can be used as light amplifiers and as sources of coherent radiation – lasers. The laser action is explained by the intrinsic optical properties of the crystal. The interband optical absorption leads to the production of free carriers in the conduction and valence bands. These free carriers constituting excited

states have relatively short lifetime and tend to recombine with emission of photons. This process is called radiative recombination or spontaneous light emission. The frequency of the emitted light corresponds to the band gap energy. A system in an excited state is stimulated by the radiation field to emit a photon and drop to a lower energy state. The rate of stimulated emission is proportional to the energy density of the radiation, whereas the rate of spontaneous emission is not. The term laser is an acronym for light amplification by the stimulated emission of radiation. Laser action is conditioned by population inversion.

A semiconductor p-n junction is a convenient system for establishing population inversion of energy levels. At a p-n semiconductor junction, the stimulated emission of radiation occurs from the radiation emitted when electrons recombine with holes. The pumping action is provided by the DC voltage. The diode wafer provides its own electromagnetic cavity, for the reflectivity at the crystal-air interface is high.

Conditioning Classical and Instrumental

Michael Domjan

Department of Psychology, A8000, University of Texas, Austin, TX, USA

A specific procedure that is intended to produce a learning effect. Conditioning procedures are typically categorized as involving either instrumental conditioning or Pavlovian conditioning (classical conditioning). Instrumental conditioning then is a conditioning procedure in which the probability of a behavioral response is altered by the presentation of pleasant (reinforcing) or unpleasant (punishing) event shortly after the response. If the response results in a pleasant outcome, it becomes more likely in the future; if the response results in an unpleasant outcome, it becomes less likely in the future.

Related Terms

[Animal learning](#); [Associative learning](#)

Description

Conditioning and learning is devoted to the study of the mechanisms of learning, primarily at the behavioral level of investigation. The focus is on observable actions and responses of human and

other animal species in response to specific stimuli and how these actions are altered by experience or learning (Bouton 2007). Learning is an enduring change in the mechanisms of behavior that results from prior experience with specific stimuli or training procedures. Behavioral changes that are not long lasting, such as those caused by fatigue or a change in motivation, are excluded from the domain of learning because they do not satisfy the criterion of being long lasting. Behavioral changes that are the result of physical maturation are excluded from the domain of learning because they do not require special training procedures.

The field of conditioning and learning has deep roots in psychology. The field dates back to the late nineteenth and early twentieth centuries and was stimulated by three separate lines of inquiry. The first of these originated with Darwin and concerned the evolution of intelligence (Boakes 1984). Before being able to comment on the evolution of intelligence, Darwin and his colleagues had to define what constituted intelligent behavior in nonhuman animals. They proposed that the defining feature of intelligent behavior was flexibility or the ability to alter behavior as a consequence of experience. Thus, intelligence was defined in terms of the ability to learn. This definition of intelligence provided great impetus for studies of learning in various animal species.

The evolution of intelligence remains an active area of investigation in contemporary psychology and behavioral ecology. The topic is now referred to as “comparative cognition” because the focus is on comparing cognition and learning in various animal species, including *Homo sapiens*. Topics considered include episodic memory, directed forgetting, spatial navigation, perceptual and abstract concept learning, serial pattern learning, tool use, and language learning (Zentall and Wasserman 2012).

The second source of interest in conditioning and learning stemmed from an interest in understanding the functions of the nervous system. This line of inquiry dates back to the work of Ivan Pavlov, who discovered that a reflex response (salivation) could become conditioned

and elicited by a stimulus (a tone) that was initially ineffective by pairing that stimulus with an effective triggering event (food). Pavlov devoted the latter part of his life to the empirical study of conditioned behavior because he viewed such investigations as informative about how the brain and nervous system work. Thus, Pavlov regarded his studies of conditioning to be an investigation of the functions of the nervous system.

Pavlov’s interest in using conditioning to uncover how the nervous system works has its counterpart in contemporary investigations of the neurobiology of learning. Great advances in the neurosciences now permit scientists to study the mechanisms of learning not only at the level of behavior but also at the level of neural circuits and neurotransmitter system, as well as at the cellular, molecular, and genetic levels (Rudy 2008).

The third major impetus for studies of conditioning and learning originated with efforts in the early part of the twentieth century to develop animal models that would facilitate investigation of specific features of human behavior that could not be studied with as great experimental control and precision with human participants. Early efforts involved developing animal models of anxiety and neurosis. Animal models continue to be used to study love and attachment, depression and helplessness, impulsivity, stress and coping, and various aspects of drug tolerance and addiction (Carroll and Overmier 2001).

Self-identification

Science

Conditioning and learning is an empirical, data-based discipline that employs the methods of experimental science. The use of experimental methods is required by the definition of learning. Learning is said to result from prior experience with specific stimuli or training procedures. Proving that a behavioral change is an instance of learning requires identifying specific prior experiences that are responsible for or constitute the cause of the behavior change. Identifying such

causal mechanisms can only be accomplished with experimental methods.

The typical learning experiment involves one group of participants that is exposed to the specific training procedure that is the focus of the investigation. Changes in the behavior of this group are then compared to that of a control group that is treated in a similar fashion but does not receive the relevant training procedure. Because learning is inferred from a comparison of the experimental and control groups, inferences about learning often critically depend on the design of the control procedure. The reliance on experimental methods has made the study of conditioning and learning primarily a laboratory enterprise (Domjan 2010). Other empirical methodologies (nonintrusive field observations or correlational techniques) often do not permit concluding that a behavior change is specifically due to learning rather than something else. Hence the study of conditioning and learning has developed as an experimental discipline. Theories that are formulated to characterize conditioning are closely related to the experimental data, and often require testing conditioning procedures against specially designed control procedures.

Characteristics

Conditioning and learning is distinctive in that it is concerned not only with human behavior but also the evolution of that behavior (Papini 2008). Hence, the discipline deals with rules of learning and principles of behavior modification that exist across a range of species including mammals and birds. The focus is on behavioral and emotional responses and processes.

The area deals with those aspects of human behavior that are not mediated by language and do not require high level linguistic competence. These features of human behavior are readily observable in children before they learn language but are not lost as people gain linguistic competence. The domain of conditioning and learning includes procedural and implicit learning that operate in the absence of conscious awareness or control (Squire 2004).

The empirical foundations of conditioning and learning are based on measurements and recordings of how often and how fast certain responses occur. Introspection and self-reported feelings, insights, and thoughts are outside the domain of this field of inquiry.

Another distinctive feature of the field is that it employs experimental techniques that involve manipulations of prior experience. This is often done in highly controlled laboratory settings.

Relevance to Science and Religion

Investigators of conditioning and learning do not consider their area highly relevant to the topic of "Science and Religion." The experiential aspects of religion, as documented by introspective self-reports, are outside the scope of conditioning and learning. Aspects of religiosity that require complex linguistic competence (beliefs and belief systems) are also outside the usual domain of conditioning, as conditioning is typically concerned with the rate and probability of occurrence of simple behavioral and visceral responses. Conditioning and learning may provide some insights into the acquisition and maintenance of religious behavior, such as prayer habits. However, few scientists in this area have addressed that topic.

Sources of Authority

The primary sources of authority in the field of conditioning and learning are the scientists who make the most important and extensive empirical and theoretical contributions to the field. Occasionally, a small body of empirical work or a novel theory will propel someone into a position of authority, but typically a more extensive body of novel empirical and theoretical work is required. The institutional authorities are editors of scholarly journals and officers in professional societies. However, they typically reach those positions of authority because of the strength of their prior empirical and theoretical contributions.

The discipline is self-regulating through peer review and peer participation in governance. Journal editors are typically selected by a committee of experts in the field. An editor's decision to accept an empirical or theoretical report for publication is usually based on the outcome of reviews by other scientists in the discipline who are experts in the topic addressed by the manuscript. Officers in professional organizations are usually nominated and elected by members of the organization, who are generally peers with shared scientific interests.

Ethical Principles

The ethical principles in the discipline are those of the ethical conduct of science and the ethical treatment of participants in experiments. These ethical principles are passed down through an apprenticeship process during graduate training that leads to a Ph.D. degree in the field. The ethical principles are also codified by professional organizations such as the American Psychological Association and the Animal Behavior Society. In addition, there are regulations promulgated by government agencies in the United States and other countries for the ethical treatment of both human and nonhuman participants in experiments involving conditioning and learning.

Key Values

The key values of conditioning and learning are those of the scientific method. Investigators are careful to focus on empirical, observable evidence. They make sure that their reasoning proceeds in a clearly spelled-out logical fashion; their inferences are closely rooted in empirical data; and their claims are empirically verified. The discipline is committed to better understanding of the mechanisms of behavior, both of human and nonhuman animals. Although the focus is on intellectual inquiry, there is an underlying assumption that an empirically based science of behavior will also enable people to improve how they treat each other and how they

interact with other animal species. Studies of conditioning and learning have made major contributions to the improvement of educational technologies and approaches to helping individuals with developmental disabilities. Studies of conditioning and learning have also contributed to the development of cognitive behavioral therapy, which is the dominant therapeutic approach in psychotherapy today. For example, this area of research has led to the improvement of treatment procedures for fears, phobias, and drug abuse (Craske et al. 2006).

Conceptualization

Nature/World

This discipline conceptualizes “nature” and the “world” in the same manner as the biological sciences in general. The relevant domain of the field consists of measurable behavioral and physiological responses. The “world” in which these responses reside includes all of the environmental, evolutionary, genetic, epigenetic, and neurobiological processes that mediate behavioral and physiological responses. Thus, the “world” of conditioning and learning is that of modern biology.

Human Being

The discipline considers “human beings” as those individuals who are members of the species *Homo sapiens* and uses the term “human being” only in that sense.

Life and Death

The discipline accepts common biological definitions of “life” and “death.” The definition of “life” and “death” is not a topic of debate or consideration in the field. The assumption is that life is necessary for organisms to learn and that learning does not occur once the organism has died. The field has not specifically considered when life begins. However, it is widely accepted that the beginning of an individual life precedes birth. In addition, it is now well established that with mammalian species, conditioning and learning can take place before birth, in utero.

Reality

For scientists in conditioning and learning, reality is that which can be observed and measured. “Reality” in conditioning and learning is similar to what is “reality” for the biological sciences.

Knowledge

For scientists in conditioning and learning, knowledge is the body of information that has (and can be) assembled based on careful empirical studies of behavior and its modification by past experience. Empirical studies are invariably guided by formal or informal theory and concepts. Therefore, those theoretical organizing concepts and terms are included in the knowledge base of the field.

Truth

What is considered to be the “Truth” in the field of conditioning and learning is obtained through empirical study and verification. Findings that are reliably obtained across repetitions of an experiment are considered to be “true.” Interpretations or theoretical concepts that are consistent with those empirical facts are considered to be “well supported” or “strongly verified.” Only in the face of overwhelming empirical data do such theoretical concepts or formulations cross the threshold to be considered “true.” Furthermore, even if a theoretical concept has achieved such strong and wide-spread acceptance, it is understood that the concept represents “truth” only as long as a more compelling explanation has not been formulated. Thus, there are no absolute truths in the area beyond empirical facts, and it is understood and expected that our conceptualizations of conditioning and learning will evolve and change as additional and better experiments and ideas are explored. One does not expect the facts about conditioning and learning to change, but concepts and theories that serve to organize the facts are likely to evolve. Furthermore, this progressive evolution of how conditioning and learning is conceptualized is expected to be an unending process. The goal is better characterization and understanding of conditioning and learning, with no a priori endpoint in mind.

Perception

Perception refers to the psychological impact of an environmental stimulus. Perception depends on the physical characteristics of the stimulus, but those physical parameters are not directly mapped onto “perception” and subsequent action. Hence, the organism’s response typically does not track changes in the physical stimulus in any simple and direct fashion.

How an organism perceives a stimulus minimally depends on how effectively the physical energy of the stimulus activates relevant sense organs. That transduction of physical energy into neural impulses is outside the domain of conditioning and learning. However, conditioning and learning is concerned with a number of other important determinants of perception. These include the motivational state of the organism. In a state of fear, for example, a number of species are more likely to attend to auditory cues than visual cues, whereas in a state of hunger they are more likely to attend to visual cues than auditory cues. Another important factor concerns the nature of the response the organism is required to make. When making directional responses (going right vs. left), mammals and birds are more likely to pay attention to where a sound originates rather than what it sounds like. In contrast, when deciding to initiate action or not (a go/no-go discrimination), they are more likely to pay attention to the qualitative features of the sound.

The perception and categorization of stimuli also depend a great deal on prior conditioning and learning. For example, in the absence of specific training, someone may categorize all shades of red as being simply “red.” However, after extensive training in art or interior decoration, one is likely to be able to make very fine distinctions among various shades of red that previously seemed pretty much the same. Conditioning and learning can substantially modify how we perceive stimuli. This type of learning allows us to detect the sounds of a malfunctioning car engine and make finer distinctions between the performance of one outstanding figure skater and another. Expert perception in reading, music, sports, radiology, and numerous other arenas all depends on

learning. What an expert sees or hears is very different from the perceptions of a novice.

Time

Time is difficult to define because it is not an observable entity but rather refers to what happens between one event and a subsequent one. Time is a widely used concept in the field of conditioning and learning. The definition of learning itself incorporates the concept of time, since learning is concerned with how experience at one point in an organism's life influences its behavior at a subsequent time point. Learning is said to have taken place if a training experience changes an organism's behavior over a fairly extended period (day, week, or year). In addition, time plays a major role in many aspects of conditioning procedures. These include the interval between training sessions (usually a day or more), the interval between successive trials (usually several minutes), and the interval between events within a trial (usually on the order of seconds). Learning is typically more effective with longer intervals between trials and between sessions.

Within-trial temporal intervals that are important depend on the nature of the conditioning procedure. In instrumental conditioning a critical temporal interval is the interval between the instrumental response and the subsequent reinforcer or "reward." Instrumental learning is impeded by delaying the reinforcer after the response is made. Temporal intervals are also important in schedules of reinforcement in instrumental conditioning.

Pavlovian conditioning involves the association of two events, conditioned and unconditioned stimuli (e.g., a light and food). The duration of the conditioned stimulus has a major effect on what is learned, as does the interval between the onset of the conditioned stimulus and the onset of the unconditioned stimulus. Another critical factor is whether there is a temporal gap between the conditioned and unconditioned stimuli. Traditional conceptions assumed that these temporal intervals determined the extent to which the conditioned and unconditioned stimuli could become associated. However, contemporary research indicates that these

temporal intervals determine *what* is learned, not whether learning occurs. More specifically, it appears that organisms learn not only whether two events go together but exactly when one event occurs in relation to the other (Amundson and Miller 2008).

Many investigators in conditioning and learning are also studying how organisms tell time and how behavior comes under temporal control. This line of research frequently employs laboratory rats and pigeons and is called "interval timing." Two types of behavioral tasks are employed in these experiments. One approach involves studying how organisms produce time intervals (e.g., learn to respond when 120 s is over). Another approach involves studying how organisms estimate time intervals (e.g., deciding which of two stimuli is the longer one). Research on animal timing is highly quantitative and involves testing precise mathematical models. There are basically two categories of timing models. One category of models employs pacemaker/accumulator mechanisms. The alternative models employ oscillator systems to provide temporal cues.

Consciousness

Consciousness is very difficult to study within the domain of conditioning and learning. Three major components of consciousness have to be considered. First, and most prominent in common parlance, is the experiential component of consciousness or feelings of awareness. The experiential component of consciousness is outside the domain of conditioning and learning since it is dependent on introspection. The second component of consciousness is verbal reports of conscious experience. Since verbal reports are behaviors that are shaped by conditioning and learning, they can be examined and analyzed by behavior theorists. The behavioral analysis of verbal behavior has been prominently pursued by B. F. Skinner and others working in the Skinnerian tradition. This approach can tell us a great deal about learning variables that control verbal reports of consciousness but it cannot inform us about the relationship of those verbal reports to the experiential component of consciousness.

The third component of consciousness involves identifying the underlying neural mechanisms and neural systems that mediate consciousness. Since conscious experience is most unambiguously identified in human subjects, the neural systems that mediate consciousness are best identified in studies with people using techniques such as functional magnetic resonance imaging (fMRI). However, the success of such an effort depends entirely on developing a valid psychological measure of human consciousness. In principle, given such a measure, one might be able to identify the brain areas and neural circuits involved in consciousness using fMRI studies with people. More analytic studies of those brain mechanisms can then be conducted with laboratory animals. Scientists pursuing this strategy have focused on trace conditioning as an animal model of consciousness. Trace conditioning experiments examine the strength of association between two stimuli (a conditioned and an unconditioned stimulus) when these stimuli are presented with a brief gap (a second or so) between them. Studies of trace conditioning in laboratory animals cannot model either the experiential or the verbal components of consciousness. Furthermore, even if trace conditioning activates brain areas and neural circuits that are similar to those identified by human fMRI studies of consciousness, one has to make the added assumption that these brain areas cannot mediate trace conditioning without conscious awareness. That assumption is probably impossible to prove. Thus, modern neuroscience approaches to the study of consciousness in animal preparations have severe conceptual limitations.

Rationality/Reason

The field of conditioning and learning accepts conventional scientific approaches to what is considered rational or reasonable. The field employs conventional practices of scientific reasoning and employs conventional rules of scientific inference in deriving conclusions from empirical evidence. The characterization of what constitutes rationality and reason is outside the scope of the field.

Mystery

The field of conditioning and learning does not concern itself with mystery.

Relevant Themes

Given the emphasis of conditioning and learning on the acquisition of behavioral and emotional responses, the field may contribute to discussion and investigation of how religious practices and experiences are learned. Three forms of learning seem especially relevant: instrumental conditioning, Pavlovian conditioning, and habituation/sensitization. Instrumental conditioning refers to situations in which a specific response is increased or decreased by the consequences of that response. Positive consequences (e.g., praise) increase the future probability of the response and negative consequences (e.g., reprimands) decrease it. Pavlovian conditioning involves the association of two events, with the result that the first stimulus comes to elicit responses relevant to the second. Pavlovian conditioning is especially relevant to the learning of emotional responses. Habituation and sensitization are produced by repetitions of an event or stimulus. Depending on the intensity of the stimulus and its rate of repetition, responses to the stimulus may decrease (become habituated) or increase (become sensitized).

One obvious area in which instrumental conditioning is involved is in the early religious training of children. Responses involved in preparing for and attending religious services are shaped and encouraged by instrumental reinforcement provided by teachers, parents, and members of the clergy. Other behavioral responses involved in religious activities (such as standing, kneeling, reciting prayers at the appropriate times) are also learned and encouraged by instrumental reinforcement (praise), and, inappropriate behavior is discouraged by reprimands.

Whereas behavioral responses are established by instrumental conditioning, Pavlovian conditioning is involved in the learning or acquisition of emotional aspects of religious experience.

These emotions come to be elicited by cues related to religious practices. Religious training and religious practice typically occurs in a distinctive context (place of worship), in the presence of specific individuals (religious leaders, teachers, or fellow worshipers), and with distinctive auditory cues (sacred music or chants), all of which can come to elicit distinctive emotions through Pavlovian associations with more emotion-arousing aspects of religious activity.

The phenomena of habituation and sensitization are highly relevant because religious practice often involves repeated exposure to the same stimuli, such as prayers, chants, and the sights and sounds of the place of worship. Emotional and behavioral responses to these repeated stimuli can change with experience through the processes of habituation and sensitization. Depending on the intensity of the stimulus and the frequency and timing of its repetitions, reactivity to these cues can either decrease (showing habituation) or increase (showing sensitization). Decreases in reactivity result in attenuated arousal and may be interpreted as being “at peace,” whereas increases in reactivity result in increased arousal and may be interpreted as “fervor.”

In the natural flow of human activities, instrumental conditioning, Pavlovian conditioning, and habituation/sensitization do not operate in isolation of one another but occur at the same time, sometimes in an interactive fashion, to determine how human behavior is shaped by learning and prior experience. It is important to note, however, that the details of how these learning principles contribute to religious practice and religious experience have yet to be carefully examined or empirically verified.

Conformons

Sungchul Ji

Department of Pharmacology and Toxicology,
Ernest Mario School of Pharmacy, Rutgers
University, Piscataway, NJ, USA

The term “conformon” was coined by combining two stems, “conform-” indicating “conformations” (i.e., deformable structures) of biopolymers and “-on” meaning a mobile, discrete material entity. Conformons are defined as follows (Ji 2012, p. 235):

Conformons are sequence-specific conformational strains of biopolymers that carry mechanical energy and genetic information necessary and sufficient to effectuate any goal-oriented movement of biopolymers inside the cell.

The first experimental evidence for the conformon was obtained in the form of ATP-induced supercoiling of circular DNA double helix in bacteria observed under electron microscope in the mid-1960s (Stryer 1995). The idea that biological properties of enzymes (also called molecular machines) may depend on the mechanical (i.e., conformational) energy stored in enzymes was first proposed by R. Lumry and others in the 1950s and 1960s (Lumry and Gregory 1986).

Cells are examples of self-organizing chemical reaction-diffusion systems that have evolved to perform (or have been selected because of their ability to perform) myriads of goal-directed (i.e., *purposive* or *teleonomic*) motions in space and time. The goal-directed molecular motions inside the living cell are carried out by biopolymers acting as molecular machines (Alberts 1998), and each molecular machine is postulated to be driven by conformons. *Conformons are to molecular machines what batteries and mechanisms are to toys.* Conformons can be generated from the binding energy of ligands as in the Circe effect of Jencks (Jencks 1975) or from the free energy of chemical reactions as in the case of stress-induced duplex destabilizations (SIDDs) in supercoiled DNA characterized by Benham (1996) using statistical mechanical language.

The molecular mechanism of muscle contraction proposed in 1974, based on the conformon concept (Ji 1974), has been supported by the experimental data obtained from the single-molecule measurements of myosin moving along the actin filament in the presence of ATP. Single-molecule experiments were made possible because of the development of the *optical tweezers* and the *total internal reflection fluorescence* (TIRF) microscopy. Employing these methods, biophysicists during the past decade have been able to measure simultaneously both the translational movement of the myosin head (which has the ATPase activity) along actin filament and the hydrolysis of ATP that powers the myosin movement. The single-molecule experimental data of Ishii and Yanagida (2007) clearly demonstrate that,

during a muscle contraction cycle, the free energy of ATP hydrolysis is transiently stored in the myosin head as *conformational strains* or *conformons* (Ji 2012, see Fig. 11.33d). The most recent and direct experimental evidence for the conformon concept was provided by Uchihashi et al. (2011) and Junge and Müller (2011). Using the high-speed atomic force microscopy, these investigators were able to *visualize* the propagation of the conformational waves (i.e., conformons) of the β subunits of the isolated F_1 ATPase stator ring. Therefore, it appears that the conformon concept has now been experimentally verified four decades after it was proposed.

The living cell can be represented as a system of molecular machines (e.g., myosin, kinesin, dynein, dynamin, RNA polymerase, DNA polymerase, topoisomerases, and ion pumps) that are organized in *space* and *time* in various combinations in order to carry out cell functions demanded by a given environmental condition. The organization of molecular motions inside the cell is a form of *work* requiring the *dissipation of free energy* supplied by chemical reactions. It is proposed in Ji (2012, Chap. 8) that the mechanism of *coupling* chemical reactions to the organized molecular motions in the living cell, i.e., *life*, is catalyzed by molecular machines obeying the generalized Franck-Condon principle imported from quantum mechanics, leading to the following scheme:

where Process 1 is governed by the generalized Franck-Condon principle (Ji 2012, Sect. 2.2.3) and Process 2 by the principles of biological evolution reviewed in Ji (2012, Chap. 14).

Conformons are the molecular objects that embody not only *energy* but also *information* necessary and sufficient for driving goal-directed molecular motions of the cell and, hence, can be viewed as the fundamental particles of life. That is, *conformons* can be viewed as the mediators of a new force in nature called *the cell force* in

analogy to the gluons mediating the strong force in atomic nuclei (Ji 2012, pp. 444–448).

Description

The nature of the mind and its functions are a central concern of Buddhist thought. In fact, in a way, early Buddhism could perhaps be considered as marking the beginning point of the study of the mind in the history of mankind. The analytical attitude adopted toward the mind places Buddhism at an interim point between science and religions, in as much as, although clearly having a soteriological orientation, the Buddhist concern with the mind and its functions shows considerable affinity with scientific methodology.

The primary role of the mind in Buddhist thought finds its expression in two stanzas that open a collection of canonical poetry, according to which the mind is the forerunner of all things (von Hinüber and Norman 1994, Stanza 1–2). According to a canonical discourse, the whole world is led along by mind, which is the one thing that has everything else under its control (Feer 1884–1898, I 39).

The early Buddhist perspective in regard to any manifestations of the mind is that, while its existence as a process is never put in question, the notion that an unchanging substance or self

can be found anywhere in the mind, or apart from it, is dismissed as mistaken. What is commonly referred to as the “mind,” should according to Buddhist thought be understood as a conditioned and impermanent process of mental events. From a Buddhist perspective, this mental flux is all that is required to account for personal continuity during life and throughout the series of rebirths from one life to another, for the margin of personal freedom to take decisions amidst a complex set of conditionings of the mind, and for the karmic retribution that arises in dependence on the ethical quality of the decisions that have earlier been taken.

The complexity of the Buddhist analysis of mental phenomena finds its reflection in the use of different terms to refer to the mind as a phenomenon. Besides “consciousness,” *vijñāna* (Sanskrit) or *viññāṇa* (Pāli), other terms of frequent occurrence are *citta* and *manas*. Although at times these three terms occur together as synonyms (Carpenter and Rhys Davids 1890–1911, I 21), taken on their own, each of them conveys a slightly different nuance.

Citta stands for the mind as the center of subjective experience, in particular in the sense of signifying the activity of the will and what could perhaps best be gathered under the term emotion.

Manas represents mind as a mode of action distinct from verbal and bodily action and as the sixth of the senses, where – besides the five physical senses of eye, ear, nose, tongue, and body – it covers the activity of thought and reflection.

Vijñāna or *viññāṇa* refers to being conscious by way of the senses. The same term also stands for the stream of consciousness that continues during a single life and through subsequent rebirths.

Consciousness is also part of an analysis of the individual into five so-called aggregates. While the first of these five aggregates corresponds to the physical body, the remaining four represent different aspects of the mind. Besides consciousness, these are feeling, perception, and volitional reactions. As an aggregate, consciousness comprises past, present, and future instances of being conscious, be these internal or external, gross or subtle, inferior or superior, and far

or near (Trenckner and Chalmers 1888–1896, III 17).

In a series of similes that illustrate the nature of each of these five aggregates, consciousness finds illustration in the example of a magic show (Feer 1884–1898, III 142). By thoroughly scrutinizing the tricks of a magician, a keen observer would find no substance in them. In the same way, on close inspection, consciousness turns out to be devoid of an enduring substance.

Besides its role in the context of the scheme of the five aggregates, consciousness stands in third position within the 12-link standard representation of the dependent arising of *duḥkha* or *dukkha* – a term whose meaning ranges from barely noticeable dissatisfaction to outright suffering as inherent features of human existence (► *Dukkha*).

According to the traditional interpretation of the 12 links of dependent arising (► *Dependent Arising*), consciousness represents what is reborn. In other words, consciousness is what descends into the mother’s womb at conception (Carpenter and Rhys Davids 1890–1911, II 63). From an early Buddhist perspective, however, it would be wrong to believe that the same consciousness passes away and is then reborn (Trenckner and Chalmers 1888–1896, I 256). Instead, rebirth takes place by way of the stream of consciousness (Carpenter and Rhys Davids 1890–1911, III 105), a changing process that is considered to be devoid of an abiding permanent entity.

Being included in the series of links of dependent arising, consciousness is evidently considered a conditioned phenomenon, dependently arisen in a way that is comparable to fire that depends on its fuel (Trenckner and Chalmers 1888–1896, I 259). Although arising in dependence on the senses and their objects, consciousness is not considered the automatic product of the existence of a sense and its correspondent object. Besides sense and object, there needs to be the factor of engagement between these for consciousness to manifest (Trenckner and Chalmers 1888–1896, I 190).

As a dependently arisen phenomenon, consciousness lacks the property of intrinsic

independence that apparently was part of some ancient Indian conceptions of a self. From a Buddhist perspective, consciousness is rather impermanent, unsatisfactory, and not-self. Contemplating the nature of consciousness in this way will free the practitioner from appropriating consciousness as “mine” or identifying with it as “I” or “myself.”

With later phases of Buddhist thought, the analysis of the mind becomes more detailed, and a range of mental states and mental factors are identified. As part of this development, the impermanent nature of the mind is given increased emphasis, leading to the theory of momentariness. This somewhat radical conception of the impermanent nature of the mind (► [Impermanence \(Buddhist\)](#)), according to which each mind moment disappears as soon as it has appeared, appears to have stimulated further developments attempting to account for mental continuity.

In the southern Buddhist tradition, this was achieved through the concept of the subliminal consciousness, called *bhavaṅga*. With some of the northern Buddhist traditions, the concept of a store consciousness, *ālaya-vijñāna*, appears to fulfill a similar purpose. This store consciousness functions as a repository for the seeds of former deeds through the process of rebirth in *saṃsāra*. Eventually, the store consciousness was considered to be the very source of the world, which thus was seen as a projection of consciousness. In other words, reality in its ultimate sense was held to be “mind only.”

The early Buddhist position, however, maintains a middle position in this respect. According to this middle position, even though the mind is considered to be of prime importance, reality is not grounded in the mind alone. Consciousness is thus merely that by which an actually existing world is experienced, any aspect of which is conditioned, impermanent, and without any abiding substance. While the mind is seen as nothing apart from an ever-changing process of mental flux, the early Buddhist conception of the mind does allow for personal continuity throughout the cycle of rebirths, for the effect of mental conditioning on decision making and for karmic

retribution, without needing to introduce additional concepts for this purpose.

Concern with the mind in early Buddhism is above all pragmatic, in the sense of focusing on what is related to the task of liberating the mind from defilements. It is only with later developments of Buddhist thought that attempts were made to develop a more exhaustive description of the mind in all its possible modes, functions, and manifestations.

Consciousness, the Problem of

Harald Walach

Institute for Information Biology, School of Social Sciences & Samuelli, The University of Northampton, Northampton, UK

Europa-universität Viadrina, Institut für transkulturelle Gesundheitswissenschaften, Frankfurt (Oder), Germany

Consciousness is an obvious reality for us, and yet the most mysterious thing. It is primary given to us. We know what it feels like to be conscious: we know that we know. We are aware of a perception of pain or joy. We consciously enjoy a particular color, or a certain wine. We know how to distinguish between our dream states and waking states. In states of lucid dreaming, some people are consciously aware of the fact that they are now dreaming. However, our culture will have us believe that all that matters, really, is matter, because we can measure, engineer, and manipulate it, to our well-being and also to the detriment of ourselves and others. Yet, what is indeed the first presupposed and given reality is always consciousness, the conscious I that reflects, perceives, thinks, negates, suffers pain and joy, desires and can let go of desires, is angry and can forgive, loves and hates, has goals and dreams out of which it constructs new insights, invents new solutions for problems, or has new ideas about old questions. The problem is how to explain human consciousness in relation to the human brain. While this dualist stance – a conscious I vis-à-vis a totally different material reality – is still defended, because it is our natural starting point and eminent thinkers like Plato, Plotinus, Saint Augustine, or René Descartes have built upon it, contemporary scholars and scientists defend some sort of materialism (Metzinger 1995, 2000). This is the doctrine that all mental phenomena are somehow derived from material reality. Often, such materialist monist positions are also called physicalist, because they insist on the fact that ultimately all phenomena boil down to

physics and will be explained in terms of scientific theory. A minority of thinkers object and insist that the problem of consciousness is so radically different from all material phenomena that it will never submit to a physicalist solution. And fewer still support a worldview that posits matter is ultimately derived from consciousness, so-called ► [idealism](#) or an idealist-monist view. Trying to explain consciousness as some phenomenon derived from matter means engaging in some form of reductionism.

Reductionism

There are various types of reductionism. They can be classified into two main types: ontological and methodological reductionism, depending on whether we mean that phenomena, processes, or events can be exhaustively explained by other phenomena, processes, or events or not. Hence, a scientific or causal reductionist view may be classified as ontological or methodological reductionism. However, reductive materialism and eliminative reductionism are tokens of ontological reductionism. *Ontological reductionism* has the purpose of providing an exhaustive explanation of some phenomenon, process, or event (the *explanandum*) in terms of another phenomenon, process, or event (the *explanans*). Accordingly, *something x* is explained in terms of *nothing but y*. In such a view, consciousness can be exhaustively explained in terms of neural activity. Also, *x* explains the occurrence of *y* and is the real nature of *y* (reductive materialism). In other words, the brain explains the occurrence of consciousness, and hence, the brain *is* the real nature of consciousness. Finally, *some unknown x* of the past has successfully been explained in terms of *nothing but y*. From this, it follows that *some unknown x* will be explained in terms of *nothing but y* in the future (Runehov 2007).

Methodological reductionism has various meanings: (1) every explanation ought to be continually reduced to the simplest possible explanation; (2) a research strategy for analyzing objects of study, such as cells, in terms of their parts, like macromolecules, as well as for

applying successful theories in one area, such as Darwinian evolution, to other areas, such as sociology or religion; and (3) it may aim to reduce a whole to a specific set of parts for a scientific purpose without claiming that this is a complete explanation. Methodological reductionism implies that *something* x is explained in terms of y but x is not reducible to y . Hence, there is no claim for exhaustiveness.

Types of Materialism and Physicalism

Materialism is the theory that everything that exists is material. According to Michael Lockwood, materialism consists of everything that occupies or takes place in space and whose existence is ultimately constituted by the properties and relations, actions, and interactions of particles and fields or whatever basic entities physics deals with (Lockwood 1989).

Materialist/Physicalist Theories of the Relationship Between the Brain and Consciousness

The first theory is known as identity theory (ID). Identity theorists maintain mental states and processes, both conscious and unconscious, are identical to brain states and processes. The identity theory of mind holds that mental processes just *are* brain processes, not merely *correlated with* brain processes. A weaker variant of this theory is the token identity theory, which implies mind-brain identities can occur only on the level of individual (token) events (Davidson and Davidson 1980).

However, we know by now that the brain uses always the same physiological principle. Inputs, whether from the senses or from brain activity itself, create an excitation in a neuron whose membrane, if adequately stimulated, will depolarize, allowing an exchange of ions with the surrounding fluid, generating an electrical activity along its own membrane. This leads to the rapid depolarization of the membrane at the axonal end of the neuron which will result in the release of transmitter substances into the synaptic

cleft, which in turn will trigger a change in membrane permeability at the other side and so transmit the stimulus. Over time, we will see the neuron depolarizing in spikes of electrical activity with a certain frequency. Nowhere in the brain do we see any of the richness of our subjective experience. All we see is confusing patterns of electrical activities and release of different classes of neurotransmitters, often even released by the very same neuron. Thus, the simple equation “brain activity is conscious activity” is seriously challenged (Searle 1992).

Advocates of eliminative materialism, for example, Patricia Churchland (1986), argue that even though consciousness is a complex issue, as an entity it is simply a misconception due to ignorance. Similar to our ancestors’ assuming the gods are angry when a flash of lightning struck and thus hypostasizing the “wrath of the gods” into a real entity, we are ignorant about what consciousness is and hence speak about it as if it were some extramaterial reality. Once we know this, our understanding, our language, and our concepts will change. “The wrath of the gods” used to be a metaphorical way of speaking about a reality that was somewhat diffuse and not known, but it was not about a real entity since “the wrath of the gods” does not exist. Similarly, consciousness is a metaphorical way of speaking about something we do not understand yet, and once we do, this way of speaking will gradually become obsolete and disappear. The problem with such a view is that there is no logical relation between what happened in the past and what will happen in the future. Also, while “the wrath of the gods” is a concept quite far from subjective experience, the conscious I is the subject of experience, and hence, the parallelism of the argument is ill founded. Also, promises of future achievements are a bit like promises of the future paradise: it has more to do with religion than with science.

Eliminative materialism has some similarity with epiphenomenalism, the view that consciousness is just some by-product of physiological activity of the brain, which is not really important. The primary function of the heart, for instance, is pumping blood. As it happens, this pumping also produces different other

phenomena, such as the heartbeat which can be heard or blood pressure which can be measured. But both of them are secondary to the real function of the heart. They are indicator of the heart's operation, but they do not have any substantive reality in and of themselves, let alone without the heart's activity. When the heart stops, the beat stops and blood pressure drops to zero. Similarly with the brain, consciousness is a by-product of neuronal, computational, and cognitive activity. It is quite conceivable that the brain could do its job also without them, but as it happens, consciousness ensues out of the brain's activity. But neither has it a decisive role to play nor does it influence the physiology of the brain (Dennett 1991).

Nonreductionist Materialist/Physicalist Theories of the Relationship Between the Brain and Consciousness

Supervenience and emergence are perhaps the two best-known nonreductive materialist/physicalist theories used today.

Supervenience states that there is a difference at the physical state level for every difference at the mental state level and the changes at the physical level of the brain cause the changes at the mental level. In its weaker form, the principle of supervenience holds that even though mental states depend on physical states, they are not reducible to them. Hence, nonreductive materialists/physicalists argue for some independence of mental life over and above the material/physical once it has been brought about. For practical purposes, it is important to establish whether consciousness, as a reality purportedly derived from brain activity, has an independent, causally relevant activity of its own. Immunity, for instance, also is the result of a complex interaction of a dense network of cells and specific molecules and produces a constant reinstantiation of the integrity of the organism vis-à-vis multiple threats. Yet "immunity" does not have any functional independence. Our everyday experience however tells us that consciousness has independent causality. For example, if we are conscious of a wish, we can execute it most of the times.

Our conscious experience does seem to have causal and functional independence and hence reacts back on its physical substrate, the brain. There seems to be a mutual causation going on. Advocates of the principle of supervenience argue that consciousness is dependent on brain activity, similarly to blood pressure being dependent on the heartbeat; however, unlike blood pressure, consciousness is a functional property of the brain that has causal relevance for the brain and at least some causal independence. Consciousness is supervenient on brain activity in the sense that it has its own causal laws and partial independence.

Theorists who favor nonreductionist materialism/physicalism and who want to give mental events causal capacities often adopt the principle of emergence.

They point to the fact that complex systems generate new functional properties, or rather, such new functional properties arise out of the complexity of their structure and are not reducible to neither of these structures. The traditional example is that water emerges out of the combination of oxygen and hydrogen atoms. However, again there are a variety of tokens of the principle of emergence: part-whole emergence implies that the whole is always bigger than its parts. Strong emergence or ontological emergence argues for independent causal powers of the emergent property, and weak emergence holds that the emergent property follows the fundamental causal processes of physics (van Gulick 2001).

Emergent properties have their own partial independence and create their own new structures. Life is such an example. If amino acids and lipids, ions, and other proteins are self-organized in structures like cells and cell organelles, life emerges. Those cells replicate and hence can create their own structures; they become sensitive in that they move toward areas that contain food and shun away from places that threaten them; they also start creating environments favorable to their survival. Similarly, it is argued, once a system becomes really complex, like the brain that can process and calculate enormous amounts of information and process huge numbers of interrelations of its elements, it is bound to develop a new system property,

consciousness. Once emerged, it starts operating according to its own newly emerged laws. With consciousness, several other phenomena arise that have not been there previously: for instance, some freedom of choice between alternatives, creative problem solving, and creativity in general; art and the appreciation of beauty; morals and ethics; and finally also religion.

Functionalism or Connectionism

Many involved in the study of ► [artificial intelligence](#) (AI) believe that computers can be just as complex as physiological brains and will sooner or later produce consciousness as an emergent property. Although such a system can be realized by any structure and any material, such an artificial neural network would probably be built out of silicon chips. Because of the binary gating of information and the logical linkage of such gating to multiple other binary elements, the storage of previous information and making it available for comparison and other activities, and finally learning and self-modification of the system, such artificial systems are already in some sense similar to the human brain. Computerized neuronal networks simulate an anatomically simplified abstracted version of physiological neuronal activity. However, so far computers have not displayed signs of consciousness.

Connectionists or functionalists argue that

- The brain is a system that has biologically grown to represent reality within a window of biological adaptation to the organism.
- This representation can be conceptualized as a series of computational operations which the neurons enact.
- Once this representational architecture of the brain becomes complex enough, it can produce consciousness.
- At some point in evolution, consciousness was useful because it helps the organism to set up a virtual reality in which actions and their consequences can be played through without any of the lethal consequences that such actions might have in reality.

- For this to happen, it is necessary for the system to represent not only the outside world but also its own states toward itself.
- This representation of the system's internal states is what we call self-consciousness or ego-consciousness.

From this, it follows, it is argued, that consciousness is not something independent with a subsistence of its own, but a virtual representation of the system that shuts down together with its system.

Counterarguments come from different sources, and there are plenty of them. Thomas Nagel pointed out that by looking at any biological system from the outside, we cannot understand how it feels to *be* this system. We will never know *what it is like to be a bat* (Nagel 1974) or like our friend or colleague because we cannot share their internal viewpoint. Our biological system does not allow us to experience what it is like to be flying in darkness on an echolot system, having the environment represented by auditory clicks, beeps, and sounds of varying ultrasound pitch and intensity. For the same reason, we would not know what it is like for our friend to see the very same picture in a gallery. Nagel's argument concerns the philosophical problem of ► [qualia](#), the specific subjective inside view of the experiential reality germane to consciousness. Another famous argument has been advanced by Jackson. Suppose you have a neuroscientist, Mary, who has learned all there is to learn about the brain and its workings and mechanisms and even the concept of color but does not have the experience thereof because she has lived all her life in a colorless, gray-shaded environment. Suppose now, after all this learning, Mary is suddenly able to see color. She will then have learned something she did not know before, namely, the experience of color. This would mean there is now something in her mind that she could not have had through all the knowledge of the brain seen from the outside, namely, the *experience* of color. This obviously means that the conscious experience is something different from the physical makeup that sustains it.

Yet, another challenge derives from Chalmers (1996). He puts forward the thought experiment

that it is possible to conceive of beings who have the very same makeup as ours, the same physiology, do the same things, cannot be distinguished from the outside and by physiological tests from us, but do not have conscious experience, so-called zombies. The very fact that such zombies are conceivable who do not share our conscious experience, everything else being equal, means, according to Chalmers, that the conscious experience itself, our qualia or our “what it is like to feel and experience something,” cannot be equated to our physical makeup.

To illustrate his objection to the suggestion that a machine could possess cognitive capacity similar to a person, John Searle put forward the Chinese room thought experiment: suppose in a room is some operator that has a set of instructions how to respond to questions written down in Chinese. All he does is hand out answer cards, also written in Chinese, without having a clue about what he is doing. The person at the other side of the room will always receive correct and understandable answers, because he or she speaks Chinese. But the operator does not. It would be equally silly to say the operator understands Chinese as it would be to say a computer has consciousness. That it is possible to simulate the human neural system does not mean that a computer neural network is equal to the human neural system. Roger Penrose has pointed out that humans can solve mathematical puzzles and problems that cannot necessarily be solved by computers, for instance, some geometrical problems (Penrose 1994).

Quantum Models of Consciousness

Some suggest that the brain might be a computer but a quantum computer, operating on quantum entanglement. Quantum physics (mechanics) describes quantum systems in terms of probability, which means that we can only specify, e.g., a probable location of the particle. The basic characteristic of quantum mechanics is that whenever we measure and/or observe a physical system, the system collapses to one of its possible

classical states. We do not know which state or states the system is in before measurement or observation takes place. Not knowing which state or states the system is in before measurement is what Niels Bohr meant when he said that *nothing exists unless observed*.

If we now imagine a more complex system, where different particles belong to one system and thereby have to be described as one, we can see that the whole system has a certain joint probability of displaying a combination of values. This joint state is prescribed by physical conservation laws, for instance, the fact that all spins have to add up to zero. If now one of the elements of the system is measured, this means that instantaneously the other element is also collapsing into an according state. Entanglement means that such values of measurements of a multielement quantum system are correlated. If one element is measured, the other element exhibits an according value instantaneously, no matter how distant in time or space it is. It is not defined which value will be seen. But once a certain value is seen in one measurement, the other measurement is known. Such an entangled system which can take on two values has been called a quantum bit or qbit. It has properties similar to a classical bit and hence can be used to encode information bitwise. But by virtue of the entangled state it is in and by the potential entanglement with other qbits, the potential computational power is infinitely greater. It has been shown theoretically that computers built out of such elements, i.e., quantum computers, can solve mathematical problems that cannot be solved by serially operating, classical computers, such as factorization problems of large prime numbers. Thereby, quantum computers seem to resemble the working of the human mind much better than classical computers. Phenomenologically speaking, when we think about something, solve problems, or are on the brink of having an idea, our mind “feels” like it would be soaring in a potential space to then “collapse” onto a concrete solution or idea. Thus, the metaphor of a quantum computer seems to be more adequate for the operation of the human mind.

The technical problem to solve is how to contain and preserve entanglement. This is a property of isolated quantum systems that has to be shielded from the environment, thermally and magnetically. For every interaction of a system with the environment leads to a decay of entanglement, the so-called decoherence. Hence, the technical realization of a quantum computer will depend on engineering entanglement to a preservation state that it can be used at will (Mahler et al. 2002).

Is it feasible to look at our brain as a potential quantum computer? Those in favor of such a view refer to the uniqueness of the human nervous system. Human neurons are built around filaments of skeleton called microtubules. These are hollow structures, built of certain proteins that come in helical orderings. Those proteins can be seen as little qbit-like switches, as the dimension of these molecules is such that they fall within the area where quantum mechanical laws have to be applied. The whole structure of microtubules forms a dense network, covering the whole brain, as they are the skeleton of all neurons. The size of those hollow resonators might be such that they could sustain quantum states via so-called long-range coherence. The basic idea is that even at very low energy, if the structure and size of a system are correct, it can couple to certain frequencies of electromagnetic radiation by virtue of a resonance effect. This can then lead to coherent states, similar to standing waves that can be produced through coherent excitations of resonant media across a whole system. The theory then maintains that the brain might be a system that can collapse quantum mechanical potential states and, by virtue of coherent excitation and/or entanglement as a process, can bring the whole system into a definite state. The moment of collapse of such a quantum potential into a definite state, exerted through some poorly understood mechanism called quantum gravity, is then supposed to be a moment where consciousness arises or is being produced by this collapse (for further details, see the discussion in Atmanspacher 2006).

Although intriguing from a speculative point of view, this model also supposes that something

completely new and qualitatively and categorically different, such as consciousness, emerges. Furthermore, a counterargument is that the brain is “too wet and too noisy” to be able to maintain quantum processes.

Some adopt the weak or generalized quantum theory in order to solve the problem. This axiomatic framework assumes that systems other than quantum systems proper can be described by a similar theoretical structure. Consequently, entanglement would be a property of real quantum systems as well as of other systems that obey similar formal requirements. It has been shown that at least some aspects of the visual system can be modeled along those lines (Atmanspacher et al. 2004). One can also conceptualize the process of conscious awareness as a quantum measurement process. If this is done, the quantum Zeno effect comes into play, i.e., if a quantum system is measured, it displays one of its potential states in the measurement process. Which one is measured is random. If the measurement process is repeated rapidly, then the probability of obtaining the very same measurement value as measured previously approaches. That means if we measure a quantum system very often and repeatedly, we raise the probability of obtaining always the same value to certainty. Similarly, if we attend to a conscious content phenomenologically speaking, the probability of keeping it before our mind’s eye becomes certainty.

However, this does not imply that consciousness operates like a quantum system. Rather, it implies that quantum theory might be applicable to other systems as well, among others, the human brain.

In order to understand how the world, including the brain, works, we have to, ultimately, apply quantum theory. Quantum mechanics presupposes an implicit dualism between a conscious measurement, the decision and act of what to measure, and the measured physical system itself. A reductionist physicalist approach to explain consciousness is only possible as long as one remains on a classical Newtonian level of description, which, strictly speaking, is not appropriate to explain consciousness.

Culture of Consciousness

There are a few other intriguing observations which lead some to considering consciousness in its own right. Let us subsume those observations under the heading Culture of Consciousness. Meditation techniques have been handed down in all cultures. They differ widely in their concretizations. But they have some very simple basic strategies in common. They all teach techniques of focusing attention, at least initially, in order to concentrate the mind. This then alters the current state of consciousness to a less scattered, more focused, and more mindful state. In such a state, one is intensely focused on one act or process such as when solving a problem. Being in such a state also enables one to keep a variety of contents in the present awareness, and it can be directed inward to understanding the present contents of our mind better. In any case, it alters the *quality* of our consciousness.

Shamanic rituals have been documented in cave paintings that can be dated back to at least the Middle Paleolithic period of the Stone Age, i.e., 300,000 to 30,000 years ago. Rituals typically involve intense concentration. The argument goes that when our ancestors tamed the fire, campfire rituals were held, which allowed youngsters to participate in an implicit training of attention. As a consequence, parts of our brain that are involved in modulating emotions, in memory formation, in empathy, and ultimately also in language formation and reasoning become more activated. Hence, the basic capacity and ensuing practice of focusing attention might have been at the cradle of human culture and of the human mind as we know it (Rossano 2007).

Thus, consciousness as a capacity can feed back on the purported substrate, the brain, to change the very substrate and, as an effect, also change its own makeup. Consciousness, then, is not only a result and product of the brain, but the brain structure is also a product of a culture of consciousness. Similarly, as our ancestors started to shape the architecture of the brain through rituals, community processes, and other ways of altering consciousness, as in meditation or ritualistic practices, we are changing, even assaulting

our brains through changes of consciousness related to changes in our culture and environment. It might still be unclear how cultural and environmental influences on our consciousness will affect our brains and ultimately human capacities. But it is clear that how our brain functions cannot be seen separately from how our consciousness operates, and our consciousness seems to have a clear and definite reverberation on the physical substrate, our brain. Jean Gebser's idea of an integral consciousness suggests that ultimately, a new culture of consciousness that will extend the faculties of our current state of consciousness might emerge.

A Potential Way Forward and Some Open Questions

Thus, at least from a pragmatic point of view, a dualist phenomenology seems to be necessary to deal adequately with consciousness. However, it need not feed into ontological dualism. Rather, one could opt for a transcendent monist type of ontology in which neither matter nor mind is primary but is derived phenomenological realities that are both ultimately caused by a unitary, underlying reality. Mind and brain might be complementary similarly to particle and wave representing light. It denotes two descriptions of one and the same thing that are maximally incompatible but both necessary for a complete description. In that sense, mental and physical descriptions are necessary and irreducible to understanding the human being. This would entail a monist ontology with a dualist phenomenology.

Still, we are left with the problem that some claim that consciousness can survive death or that people who have been physically dead and resuscitated sometimes report veridical information received while their brain was physiologically inactive. It is these phenomena that have contributed to the feeling that apart from individual ego-consciousness, there is a spiritual side to the person that has been termed soul and is supposed to be different. Often such metaphysical notions have been merged with a dualist stance of the mind-body problem. It might be more useful to disentangle the problems at this point and note that this question of a potential transindividual

consciousness or soul has not received adequate attention. Materialist and reductionist thinkers would of course state that these questions have become obsolete with our modern views and a scientific approach. Those who focus on phenomena point to the fact that the modern theories ignore such phenomena. Perhaps, it is necessary to document the purported phenomena well before they can be used for scientific argument and keep theorizing open ended for the time being.

Constructive Theology

Joerg Rieger

Perkins School of Theology, Southern Methodist University, Dallas, TX, USA

Related Terms

[Christian theology](#); [Dogmatic theology](#); [Systematic theology](#)

The term “constructive theology” is often used synonymously with the terms Christian theology, systematic theology, or dogmatic theology and connotes an understanding of theology as a discourse that is both constructed and engaged in ongoing construction. Constructive theology is, therefore, a discourse that is always in process and open to interaction with other forms of knowledge, including knowledge produced in the social and natural sciences.

One of the differences between constructive and systematic theology is that the latter seeks to develop a system, based on philosophical approaches or particular themes or insights, which provides a comprehensive framework for theological topics. Constructive theology, on the other hand, rejects closed systematic frameworks in favor of more open ended reflections. One of the differences between constructive and dogmatic theology is that the latter often focuses on doctrines and concepts with little attention to matters of everyday life and experience. Constructive theology, in contrast, links doctrines and concepts with particular expressions of life.

The term constructive theology is relatively new. It has been in use since the 1980s. There are several prominent professorships in theology in the United States, which have adopted the term, including professorships in constructive theology at Drew University and the United Seminary of the Twin Cities, occupied by Catherine Keller and Eleazar S. Fernandez, and the Wendland-Cook Professorship in constructive theology at Perkins School of Theology, Southern Methodist University, occupied by Joerg Rieger.

While the term constructive theology has become a constant in contemporary theological discourse, it still rarely occurs in theological dictionaries. One exception is the *Evangelical Dictionary of Theology*, which defines the term in relation to the development of a particular workgroup on the topic of constructive theology, said to be concerned with “clarifying how the church can meet and shape the actual world with a Christian message freed from bondage to arcane models of vertical transcendence.” The *Evangelical Dictionary* accuses constructive theology of unwittingly deconstructing and demolishing biblical faith, implying that biblical faith is only supported by more conservative theological models (Elwell 1984, 269, 271).

Although the agenda of the so-called Workgroup on Constructive Theology has changed over the years, the workgroup still exists, and its theological production over the past four decades helps define constructive

theology better than any definitions that individuals might give. The theological orientation of the Workgroup on Constructive Theology has morphed from an initial commitment to theological liberalism and critical modernism in the 1970s and 1980s (Hodgson and King 1982) to engagements with liberation traditions and postmodernism in the 1990s (Chopp and Taylor 1994). Since that time, the workgroup, which is currently made up of a diverse group of about 60 theologians working in the United States, has grown increasingly complex in its theological orientation. In one of its most recent textbooks, it has developed a new concern for traditional theological roots and developments, as awareness of these roots is weakening in the academy and with students (Jones and Lakeland 2005).

The large variety of theological perspectives of the Workgroup on Constructive Theology today includes liberals, postliberals, and liberationists; feminist, Latino/a, African American, neo-orthodox, and process theologians; historicists, pragmatists, and cultural theorists; postmodernists of Derridean and Marxist varieties; and postcolonial theologians (Jones and Lakeland 2005, 5). For an example of workgroup members engaging postcolonial methods and topics, see the volume *Empire and the Christian Tradition* (Kwok, Compier, and Rieger 2007). The publisher of choice of many theologians identifying with the methods of constructive theology has been Fortress Press.

In one of its most recent collaborative publications – the fourth in a series of textbooks produced over 35 years – the members of the Workgroup on Constructive Theology note “that religious beliefs have the power to tear down cities as well as build up nations, that theology has the capacity to save lives as well as to take them.” In short, “theology really is a life-and-death endeavor” (Jones and Lakeland 2005, 1). This is the most crucial concern of contemporary constructive theology; any engagement with other forms of knowledge, including the knowledge produced by the sciences, needs to be seen in terms of this life-and-death endeavor.

Other constructive theologians have expressed the task of constructive theology in the following ways:

Catherine Keller notes that “faith is not settled belief but living process. It is the very edge and opening of life in process. To live is to step with trust into the next moment: into the unpredictable” (Keller 2008, xii). The alternative, rejected by constructive theology, is a belief in God that assumes that it has it all figured out. The task of constructive theology in this account is to deal with faith as a dynamic entity and to liberate it from the misunderstanding that it can ever be fixed and static.

According to David Jensen, another professor of constructive theology at Austin Presbyterian Theological Seminary, uniformity of theological details is not the goal of constructive theology. In an edited volume on the doctrine of the Holy Spirit, Jensen identifies the “bedrock of conviction” of progressive theology in the following way: “As the Spirit gives life, we are to seek life amid the forces and spirits that threaten life in our day” (Jensen 2008, xvii). Because constructive theology engages life, it finds itself in opposition to all that endangers life.

Constructive theology is, therefore, never a merely descriptive endeavor. It is an effort to understand and construct theology in the present, imagining what life-giving faith might look like.

While the term constructive theology is often used in relation to progressive theology in the United States, since 1995 a *Journal of Constructive Theology* is being published in South Africa by the Centre for Constructive Theology at the School of Religion and Theology (SORAT) at the University of Kwazulu Natal. The contributions published in this journal bring together classical theological issues and the struggles of everyday life, including social tensions affecting South African society and other matters of public concern, like the AIDS crisis. The subtitle of the journal is “Gender, Religion and Theology in Africa,” and the editors are Professors Isabel Apawo Phiri and Sarojini Nadar of the University of Kwazulu Natal.

Constructive theology in all this different contexts is characterized by a concern for the

constructed nature of all theology and a commitment to the ongoing constructive task of theological work. It takes seriously the insight that all reflection and thought, theological and otherwise, are related to life and that there is no escape. This is true also for beliefs and faith. As the theologians of the Workgroup on Constructive Theology have put it: “Beliefs are...profoundly shaping not only how we perceive our world but also how we engage and respond to it” (Jones and Lakeland 2005, 13). At the same time, our beliefs are also shaped by our perceptions and engagements of the world.

Critics of constructive theology worry that emphasizing the constructed nature and the constructive task of theology will lead to theological relativism. Yet relativism is not the necessary result of an appreciation for the relativity of faith, belief, and theological reflection. On the contrary, overlooking the relativity of faith, belief, and theological reflection often results in approaches that universalize relative positions. While it has often been taken for granted, for instance, that the theologies produced by white male Europeans or Americans are universal, we are beginning to understand that these theologies are also relative, as they are produced in particular places and times by particular individuals and groups. Similar insights apply to the work of scientists as well (Harding 2008).

Understanding how faith, belief, and theological reflections are always responses to particular challenges of life and to particular experiences of God is a first step toward the formation of common concerns and denominators that bring together different approaches (Rieger 2001). More specifically, examining faith, belief, and theological reflection in the midst of the struggles of life that affect us all, albeit in different ways, allows for the development of constructive theologies that acknowledge relativity but do not end up in relativism. Postcolonial theologies, for instance, are constructive theologies that have developed particular ways of dealing with relativities imposed by the powers that be while bringing together the concerns and life experiences of the many who

have experienced the effects of these powers in their own bodies.

Taking seriously the constructed nature and the constructive task, at the core of the definition of constructive theology, can open up new possibilities not only for the work of theology but also for collaborative projects that combine insights from theology and the social and natural sciences. In the process, these disciplines can develop a new sense for the contingencies of everyday life, which does not neglect the big questions of truth but locates truth in particular contexts.

(Epistemological) Antirealism; Idealism

Description

The collective term “constructivism” (from Lat. *construere*: to construct) covers all theories of cognition, which particularly emphasize the active contribution of the subject in the process of cognicizing. Thus, “constructivism” is used to group together various epistemological views in philosophy, psychology, sociology, theory of sciences, etc., which maintain that cognition or knowledge is not, or not so much, passively received, but actively built up and constructed.

Beyond this general characterization, several basic types of constructivism can be distinguished, namely, *Radical Constructivism*, *moderate constructivism*, *global and regional constructivism*, and *cultural and naturalistic constructivism*.

Radical and Moderate Constructivism

Radical constructivist views reject cognition as being sufficiently determined by the external world, independent of the mind, so that warranted or justified beliefs about the world can be achieved. However, radical constructivists usually do not deny the existence of an external world like ontological antirealists do. Rather they deny that anything definitive can be known about it, which is a view more in line with an

epistemological antirealist view. Moderate constructivist views acknowledge the active role of construction in our belief-building processes, but also hold on to the possibility of cognitive relevant feedback from reality, in terms of falsification or validation. According to this view, the accurate recognition and description of objective facts and contexts is, at least in principle, possible, even though human knowledge remains conjectural and provisional.

Global and Regional Constructivism

In addition, global and regional types of constructivism can be discerned. Many philosophers or scientists are not generally constructivists, but hold constructivist views with regard to particular regions of reality or subject matters under discussion, such as, for instance, moral or aesthetic properties, mathematical objects, natural kinds or species and, in principle, anything.

Cultural and Naturalistic Constructivism

Finally, there are cultural and naturalistic versions of constructivism. While cultural variants of constructivism maintain that cognition is mainly a sociocultural product (see the note to T. S. Kuhn below), naturalistic variants put emphasis on the evolutionary, biological, or neurological conditions and foundations of human cognition.

Brief History

Constructivism has a long history, which can be traced back to medieval *nominalism* and ancient *skepticism*. However, constructivist views have become more influential only since the seventeenth and eighteenth centuries, when British empiricism, and subsequently German idealism, emerged. Particularly D. Hume and I. Kant are to be mentioned as influential precursors to and pioneers of contemporary constructivism. According to Hume, all “ideas” held in the human mind, of any level of complexity, can be derived from simple “impressions,” i.e., mental reconstructions of sense perceptions, which we interconnect in a habitual way. Moreover, since, according to Hume, all we have are perceptions and inferences

do not lead beyond perceptions, but just to these again, we cannot know whether there exists a world independent of our perceptions and what it would be like. Kant argued that the schemes of ordering which constitute human cognition (i.e. “categories” such as substance, relation, causality, etc., and the “a priori forms of intuition,” i.e., time and space) are located in the cognicizing subject rather than in the external world. For that reason, empirical knowledge does not reflect the world as it is in itself, but only the way it appears to us, i.e., the “world of appearances.”

In the recent history of philosophy, attempts made to give a new foundation to mathematics, in view of the foundational crisis of mathematics, have been labeled as “constructivism.” For intuitionists (L. E. Brouwer, A. Heyting) and subsequent constructivists (P. Lorenzen, K. Lorenz), mathematical objects are only considered to exist if it is possible to specify an effective procedure for constructing them. In contrast, indirect proofs of existence are rejected as being inadequate.

In the second half of the twentieth century, within epistemology and the theory of science, two schools have emerged which are explicitly referred to as “constructivism”: Erlanger constructivism and Radical Constructivism.

Erlanger Constructivism

The Erlanger school of constructivism pursues a program of developing a “reasonable language” – especially a language of science – in a methodical and noncircular way. This concept was introduced by W. Kamlah and P. Lorenzen with their formative work “Logische Propädeutik” (1967) and later continued by K. Lorenz, J. Mittelstraß, and others. Some representatives confine themselves to (re-)constructing the language of science, while regarding our everyday language and lifeworld (“Lebenswelt”) as being an inescapable starting point or “prescientific a priori.” Others, however, hold our daily practice of language to be both capable of and in need of justification.

Radical Constructivism

Radical Constructivism can be characterized as a global and naturalistic version of constructivism. Its most well-known representatives (H. Maturana, F. Varela, H. v. Förster, E. v. Glasersfeld) reject *direct realistic* as well as *representational* views of cognition and support that stance with philosophical arguments as well as with evolutionary, neuroscientific, and biological findings. The resulting antirealistic attitude leads radical constructivists to a merely *instrumentalist* view of cognicizing, according to which our everyday as well as our scientific cognition does not reveal what the external world is like (so that we would “know that”), but what is *viable*, i.e., “fitting” to our experience, and benefits our survival in some way (so that we have “know-how”). Representatives of Radical Constructivism within neurosciences (G. Roth et al.) do not regard reality as a construction of the “I,” but rather the individual “I” as an evolutionary useful, even though illusionary, construction of the brain.

Discussion and Impact of Constructivism

While Radical Constructivism has numerous followers among biologists, psychologists, sociologists, and educationalists it has few supporters among philosophers and is regarded as controversial by them. Radical Constructivism requires a consequent departure from any kind of (e.g., critical or scientific) realism, which we usually take for granted in our everyday life and often also in the practice of science. This departure, however, is not easy to maintain, since radical constructivists cannot easily do without statements about how things really are, for instance, when they argue for an antirealistic view of cognition against the realists. Hence, they should not rely on findings of the empirical sciences, for if these findings should give support to Radical Constructivism, they would require a realistic interpretation. Apart from that, it is not easy to see which kind of philosophical arguments in fact support Radical Constructivism successfully. Thus, constructivist views of cognition, whether radical or moderate, global or regional, cultural or naturalistic, seem to be

primarily motivated by an alleged lack of plausibility on the part of realistic alternatives. This eventually leads to the question of whether constructivist views of cognition can offer an overall more plausible explanation of our experience than alternative theories. This issue, however, may vary drastically across different subject areas and remains an ongoing discussion.

Constructivist considerations play an important role in the philosophy of religion and in religious studies. The formation and development of religious traditions owe themselves to complex processes of sociocultural construction (as well as criticism), which are explored and reconstructed by the history, psychology, and sociology of religion and other subdisciplines of religious studies. In principle, constructivist considerations may serve to criticize as well as to justify religious beliefs and practices. In the context of functional explanations, for instance, religious beliefs and practices were seen to be a product of socioeconomic conditions (K. Marx), infantile illusions or projections (S. Freud), or society-stabilizing mechanisms (E. Durkheim). However, defenders of religion can also rely on constructivist considerations. When it comes to the problem of diverging or competing truth claims among different religious traditions, to name only one example, religious pluralists (J. Hick, P. Knitter et al.) argue that religious beliefs and concepts can be understood in terms of an experience of a transcendent and ultimate reality, in itself incomprehensible, which is perceived and conceptualized differently within various religious traditions. However, the above mentioned explanations, as well as many other explanations of religious phenomena, often have very little support from empirical data.

[Enactivism and Buddhism; Neurobiological constructivism and insight meditation](#)

Description

Following recent developments in cybernetics and general systems theory (Ashby 1956; Foerster 1981), in the 1980s an independent theory of biological epistemology was developed in the cognitive sciences under the paradigm of

self-organization. In this theory, cognition, mind, truth, and consciousness are no longer seen as something absolute, but emerge out of the flow of material and energy in a process of constant becoming. The basic assumptions of this approach (Maturana and Varela 1987) are as follows:

1. Cognition is conceptualized as an embodied process that is based on the fact that organisms are intertwined with their environments through their actions and perceptions. Each individual organism actively produces its own reality in the act of perception. “Every act of knowing brings forth a world.” (Maturana and Varela 1987: 26) There are as many realities as there are different organisms.
2. An organism’s actions determine what it perceives. Perception shapes cognition and is encoded into the neurological structures of living organisms. In turn, their cognitive structure shapes their actions. This self-referential circle of perception and action configures reality as in a *self-fulfilling prophecy*.
3. Different organisms link their behavior, leading to a qualitatively new form of behavior, i.e., the *production* of signs that coordinate behavior. The ability to use these signs in isolation from their immediate contexts results in the development of a new domain of action-language. Words elicit words. Communication elicits communication. Thus, along with language, the mind also develops primarily from the process of forming social connections between organisms.

In “languageing,” constructs such as the “I,” “self,” “meaning,” “sense,” and “nonsense” evolve. The associated human condition has an inherent risk of deep alienation and the suffering that goes with it. The alienation results from the fact that the praxes of perception and action become disconnected from the social and bodily origins on which they depend. This gives rise to an implicit ethical dimension. Love thus appears to be neither an abstract concept nor simply a form of sexual desire. Rather, it now appears as the basic emotion that makes humans human. In the words of Maturana and Varela:

What biology shows us is that the uniqueness of being human lies exclusively in a social structural coupling that occurs through languaging, generating (a) the regularities proper to the human social dynamics, for example, individual identity and self-consciousness, and (b) the recursive social human dynamics that entails a reflection enabling us to see that as human beings we have only the world which we create with others – whether we like them or not. Biology shows us that we can expand our cognitive domain. This arises through a novel experience brought forth through reasoning, through the encounter with a stranger, or, more directly, through the expression of a biological interpersonal congruence that lets us *see* the other person and open up for him room for existence beside us. This act is called *love*, or, if we prefer a milder expression, the acceptance of the other person beside us in our daily living. This is the biological foundation of social phenomena: without love, without acceptance of others living beside us, there is no social process and, therefore, no humanness. (Maturana and Varela 1987: 246)

At the end of the 1980s, an interdisciplinary group of scientists working with Varela et al. (1991) began to investigate to what extent the epistemology and ethics of neurobiological constructivism and the concept of embodied cognition show parallels with Buddhism.

Buddhist teachings, and in particular the early Buddhist system of Theravada Buddhism, is also a self-referential epistemological system. In this view, it is also the perceiver himself who creates the conditions of his perceiving and knowing, in his acts of perceiving and knowing. In contrast to most of the Western epistemological systems, which have focused on the search for something invariable or constant, be it an immortal soul, a universal physical constant, or an absolute truth, here reality becomes something dynamic that organizes itself in a process of constant arising and passing away, a mental and physical flow. Reality, perception, and mind develop in a creative process of continuous embodiment.

A highly fruitful new research domain that has become known as “neurophenomenology” has developed out of the meeting between neurobiological constructivism and Buddhist insight practices. This new domain is learning to take first-person methodologies seriously as

a scientific approach to the study of cognitive processes. Using this approach it is possible to relate controlled self-observation of awareness processes to the spatiotemporal patterns of neuronal dynamics in a productive way (Petitot et al. 1999).

Now, for the first time, a research program has been developed that, in contrast to the research on meditation carried out in the 1970s and 1980s, adheres to the true goals of Buddhist insight practice – i.e., the transformation of the self through self-knowledge. In almost all forms of Buddhist meditation, mental concentration (*samadhi*) is not an end in itself, but simply a means to gaining insight into the changeable and therefore essenceless nature of the self (Lutz et al. 2007).

Self-identification

Science

Although some researchers of this school practice or have practiced Buddhist meditation themselves, they see themselves mainly as scientists who are serious about complying with the high standards of scientific practice and reflection. Theories and concepts must stand the test of critical discussion. Hypotheses derived from them must be expressed in a way that allows empirical falsification.

Religion

All forms of communication are considered to be biologically and socially constructed and must therefore be seen as relative to an observer. This kind of stance stands in fundamental contrast to all religious dogma that claims to be able to make statements about the Absolute. However, in its epistemological reflections, neurobiological constructivism is faced with problems of form that are related to those encountered in mysticism. Like mystic reflection, it comes up against the problem that it must assume the unity of a difference, but cannot observe this unity with the senses or describe it through the medium of language.

Characteristics

A new branch of research has emerged which is linked to the name Thomas Metzinger and based on the perspective of analytical philosophy of mind, which also has a certain affinity with Buddhist insight practices. Here again we find the notion that the I or self is an illusion (“nobody ever had or was a self,” Metzinger 2004). However, in contrast to the view presented here, this model has shortcomings that prevent it from satisfactorily integrating the phenomenological perspective of conscious experiencing into research.

There are also well-founded approaches that bring together Buddhist insight practice and Western cognitive science in psychology (e.g., Shapiro 1980) and neurology (c.f. Austin’s (1999) excellent book). However, in terms of first-person methodologies, these approaches are not as well developed and theoretically consistent as that presented in this entry.

Relevance to Science and Religion

Dialogue with leaders of Buddhist schools is actively sought. However, a strict logical differentiation is made between scientific and religious descriptions (see, e.g., Varela and Engel 1998).

Sources of Authority

The research network of the neurobiological constructivists sees its foundations as being in the first and second generations of cybernetics, which rendered it possible to give formal descriptions of recursive systems (Norbert Wiener, William Ross Ashby, Gregory Bateson, Heinz von Foerster, etc.). The main authority on the phenomenological perspective is Edmund Husserl, who developed and carried out a program of scientifically based phenomenology. Among the neuroscientists we must mention all those who have continued to develop the paradigm of connectivism. For the dialogue

with Buddhism, the best authorities are teachers who follow a tradition that places the emphasis more on the practice of meditation than on theoretical issues.

Ethical Principles

The main principles and values are academic and intellectual integrity and the attempt to embed the results of neuroscientific research and cognitive science in an overarching ethical framework.

Conceptualization

Nature/World

The world and nature are seen as the horizon of operationally closed cognitive systems. This horizon must be presupposed but can never be reached. Meaning can only refer to meaning. Epistemically there is no access to the world outside of the limits of meaning set by one’s own cognitions. These limits can be expanded by training (e.g., by Buddhist meditation).

Human Being

Human beings are conceived of as biological, physical, and social phenomena. These three spheres are seen as inextricably linked. Since social praxes are seen as being embodied in the body and brain, this inevitably results in an implicit ethical dimension. The human mind – and therefore also happiness and unhappiness – is created by a person’s own insight practice. Love and compassion, understood as the feeling of permitting others to be worthy and accepted alongside oneself, thus appear as a biologically inherent human potential for self-transcendence.

Life and Death

In both neurobiological constructivism and the early Buddhist scriptures, the process of becoming and thus also the process of becoming conscious are described as a circular psychosomatic process. The inescapable consequence for

the process of becoming is that the actions of an organism determine what it perceives. The mode of perception shapes the potential of future cognition. Both are inscribed in the neurological structure of the perceiving organism and influence its future being and experiencing.

The Buddhist teachings describe this process as the law of dependent arising (*paticca-samuppāda*). The mind determines the body; the body determines the mind. Sense-based consciousness (*viññāna*) gives rise to the sensations (*vedanā*) in the body. The sensations produce a reaction (aversion or desire) that is in accordance with earlier conditioning of the mind (*saññā*), with meanings being attributed to the sensations. This reaction has a corresponding effect (*sankhāra*). As a result of this effect, a new sense-based consciousness arises. In *sankhāra*, the process of the mind “forming” and “being formed” is embodied. In a continuous process of becoming, mind materializes itself and is manifested as a physical structure (*nāma-rūpa*). The physical body with its cognitive capacities and its environment thus appears as the embodiment of past mind-body reaction patterns and at the same time creates the conditions for the future process of the mind.

The Buddhist concept of rebirth assumes that this process does not cease at death, but is perpetuated via a never-ending chain of further subsequent life forms. At the current state of the art, neurobiological constructivism does not have any evidence for reincarnation. Its descriptions thus refer only to the cognitive nexus of the mind-body processes of a single biological, human individual.

Reality

Reality is nothing other than the operation of operationally closed systems in the space of the present. However, reality cannot be accessed directly by observation or communication, but can only be described or deduced in retrospect.

Knowledge

Knowledge is a sphere of sense operations produced by communication in which models of reality develop. These models or programs are

conditionings that enable systems to cope with the world in their own specific ways in accordance with the action tendencies that arise.

Truth

Truth is a sense operation of the social sphere produced by communication in which knowledge is labeled with the values “true” or “false.” The possibility of an absolute, final truth is thus excluded for the domain of language.

Neurobiological constructivists must also confront the circularity of their reasoning, which becomes a problem when the observer is integrated. Attempts by the traditional epistemologies to clarify the role of the observer led to the paradox of the subject-object problem. All attempts of a subject to make itself an object are doomed to failure, since the object is now in fact the subject and the explanation thus collapses into either a paradox or a tautology. What remains, in the final analysis, is only the subject’s attempt to substantiate itself. However, to do so it would have to be able to step outside of itself – to assume an objective position – which is impossible, since the world can only be observed within the world.

Although those who support this position consider it to be science, scientific theory-building in the domain of constructivist epistemology can no longer be justified using a general “Logic of Scientific Discovery” (Karl. R. Popper). Even if this had not already been clear before, the foundational theories developed by the mathematician Gödel show that if a logical system attempts to prove itself, this must inevitably result in contradictions. However, since science is obviously empirically successful even without demonstrating its logical consistency, the question of its justification must be turned round. How does science still manage to generate its subject matter and truths – and answers to the question as to its own means of gaining insight – if they are no longer justifiable by transcendental reasoning (Kant) or logic? The answer to this question is revealed by the instruction “observe the observer” or, for science as a system, “how systems form due to the observation of observations” (Luhmann 1998, *my translation*). Thus, circular

justifications are now admissible, which are an important innovation in comparison to classical epistemology. As in “naturalized epistemology” (Willard V.O. Quine), it is now accepted that assumptions regarding the premises of knowing can themselves be influenced by empirical research. The principles and premises of the research itself can therefore be conditioned by the social praxis of research. We thus arrive at an eigen theory of the process of knowing that has the task of explaining how insight develops out of itself and finally renders self-understanding possible. The result is an epistemology in which the traditional subject-object distinction becomes secondary, the focus shifting instead to the process of the development of cognition and insight. The question is now no longer “What is the observer?” but “How does the observer arise?” The experiencing subject and the objects of perception and knowledge are therefore now no longer considered to be something substantial or absolute, but appear to create each other in a dynamic process of emerging observation.

The task of a complete eigen theory of knowledge is to show, consistently with our empirical experience, how the process of gaining insight into a reality creates a reality in which self-understanding is possible.

Perception

Perception is understood as a process in which an organism or system permits itself to be perturbed and provoked into action by the environment in accordance with its own cognitive structures and reaction patterns.

Time

Cognitive systems are time-based systems which generate certain rhythms and therefore their own system times through their own operations. The present appears not as a point but as an extended structure within physical time (cf. Varela 1999).

Consciousness

Neurophenomenological studies have demonstrated that there are structural parallels between the dynamics of neuronal processes and the change in the contents of consciousness.

However, the secret of consciousness has therefore still not yet been revealed. The supporters of this research tradition generally assume that consciousness cannot be conceived of as an entity located within the brain. Rather, it is assumed that consciousness must be understood as a process and is not therefore to be found at a distinct location (cf. Cosmelli and Thompson 2010). Here consciousness is seen neither as a thing nor as a “something,” but as an emergent phenomenon which arises out of a relational dynamic that generates itself. This position is consistent with Buddhist teachings, according to which beyond the law of dependent arising (*paticca-samuppāda*), there is no substrate of a soul or essential personality.

Rationality/Reason

In both neurobiological constructivism and Buddhism, human rationality is seen as a precondition for being able to know oneself. Nonhuman animals do not have the capacity to reflect upon their own process of self-knowledge.

Mystery

The epistemologies of the Buddhist teachings and radical constructivism have two implications which distinguish these two systems radically from most other philosophical or religious systems:

1. In neither of these systems of thought, there is a fully explicated absolute truth or an explicit meaning to our experience. All attempts to determine a truth with absolute validity are rejected by these two systems as an illusion. Maturana and Varela speak of the *nonteleological nature* of all biological forms, and the Buddhist teachings repeatedly emphasize the *essenceless* and *lack of substance* of all our sensory and cognitive processes.
2. There is an unexpected depth dimension to groundlessness, the nonrational basis of our being. An implicit order is revealed in human existence that is beyond all external prescripts and rules. The biology of incarnation contains an ethical dimension, according to which love is recognized as the implicit basis of human praxis. In Buddhist teachings,

the spiritual dimension of human existence is realized as loving kindness (*mettā*) and compassionate love.

For neurobiological constructivism, the mystery of life is manifested implicitly in our knowing how we know. One can transcend one's own being by understanding on a deep level that mind is not to be conceived of as different from the relational matrix actualized through one's own life praxis.

In contrast, the goal of the Buddhist teachings is to completely overcome human suffering as expressed in the "four noble truths" (*catvāri āryasatyāni*): the truth of suffering (*dukkha*), the truth of the cause of suffering, the truth of the end of suffering, and the truth of the path that frees us from suffering. On a superficial level, the truth of suffering appears to be the overcoming of uncertain social conditions, illness, death, etc. However, in the Buddhist doctrine, the truth of suffering has another, deeper dimension, which only becomes evident in the deep experience of *anattā* (not self), the experience of the essencelessness of all phenomena. In *anattā* we find that all attempts to introduce some kind of meaning inevitably find their antithesis in the reality of impermanence – i.e., finally in death. Only in the experience of *anicca* (impermanence), the inconstancy of all being, does the ethical dimension of the Buddhist teachings become comprehensible. Since our strivings cannot have a final goal – since any goal would unavoidably dissolve in the absolute certainty of death – the ethical gain of any action must lie in itself. All actions must be perfect, without any vestige of a transcendental expectation or a meaning beyond the lived reality. The author of the action must become completely at one with his experience. Any vestiges of a desire for something that is not being lived can never be fulfilled, nor can lingering aversion to what has been lived be discharged. The past is gone forever.

Only in the conceptual vacuum of the "ego-self" (*attā*) does the claim to having had a life other than the one that has been lived appear. It is out of this discrepancy that all the neurotic constructs of bitterness, disappointment,

and discontent and also feelings such as guilt and alienation arise. When we are attached to these states, the gap between being and experiencing increases. Openness toward others (the *Mitwelt*) is eclipsed by our aspirations to the confirmation of our concepts. Our actions are simply guided by the egocentric motives of the fantasy worlds of our "egos." In the Buddhist view, the solution to this dilemma lies in "destroying the ego," the interfering factor that prevents us from being in contact with reality. The separation between subject and object falls away, and action and perception are once more in harmony. The ethics are implicit in the living of this unity. They are lived in the awareness that all phenomena exist only in relation to other phenomena. In Buddhist terminology the three "sublime attitudes" (*brahma-vihāra*) are termed *mettā*, *muditā*, and *karuṇā*, which can be roughly translated as loving kindness, empathetic joy, and compassion. Here the knower becomes aware of the relativity of his/her own reality and beliefs. The idea of an inherent and independent soul is replaced by insight into the relational dynamics of one's own consciousness. At this level the meditative practices of self-awareness are no longer seen as a withdrawal from responsibility toward the world, but lead to a new openness to the *Mitwelt*.

With the attainment of *nibbāna* (in Sanskrit "nirvana"), the Buddhist teachings assume that there is experience that is beyond dependent co-arising. In the *Dhammapada* we read, for instance

A monk with his mind at peace,
going into an empty dwelling,
clearly seeing the Dhamma [law of nature] aright:
his delight is more than human.
However it is,
however it is he touches
the arising-and-passing of aggregates:
he gains rapture and joy:
that, for those who know it,
is deathless,
the Deathless.
(*Dhammapada* 373/374, Translation: Venerable
Thanissaro)

Since according to Buddhist doctrine, the experience of *nibbāna* lies beyond both the

five senses and all conceptual ideas, it cannot be captured in scientific terminology. Thus, the reality of nibbāna cannot be scientifically proven, and thus, it cannot be confused with the states of deep contemplation experienced by meditators, which are now demonstrable using the imaging procedures of modern neuroscience.

Relevant Themes

Comparison of neurobiological constructivism and Buddhist doctrine has proved fruitful in many ways. Also for those who would wish to view Buddhism as a religion, the Buddhist teachings can, to some extent, be seen as compatible with the neuroscientific worldview. The doctrine of the nonexistence of the soul is highly consistent with several positions within the philosophy of mind and the cognitive sciences. Buddhism would seem to be an interesting dialogue partner precisely because it can help not only to develop a new ethical position that is far from nihilistic but also to create hopeful basis in our lifeworlds that might help us to become reconciled to the idea that our egoic experience is merely an epistemic misconception. To quote Francisco Varela:

At very least, the journey of Buddhism to the West provides some of the resources we need to pursue consistently our own cultural and scientific premises to the point where we no longer need and desire foundations and so can take up the further tasks of building and dwelling in worlds without ground (Varela et al. 1991: 254).

College, Mount Berry, GA, USA

Of or related to contemplation – that is, the act of focusing one’s attention upon something in a thoughtful, purposeful, and sustained manner. In Christian traditions contemplation, often involves intentional reflection upon one’s own inner experiences for the purposes of gaining a more profound understanding of the self, the world, and God. Other rituals of devotion often accompany Christian contemplation; examples include prayer, chanting, the reading of scripture, and specific body positions such as bowing on one’s knees.

Description

Control theory is an interdisciplinary branch of engineering and mathematics that deals with the behavior of dynamical systems. When one or more output variables of a system need to follow a certain desired reference over time, a controller manipulates the inputs to a system to obtain the desired effect on the output of the system (► [Action Control](#)).

Cybernetics is closely related to control theory and systems theory. It is the interdisciplinary study of the structure of regulatory systems. The term “cybernetics” was coined in 1948 by American mathematician Norbert Wiener (1894–1964) from Gk. *kybernetes* “steersman” perhaps based on 1830s French *cybernétique* “the art of governing” (Wiener 1948). Both of them became a discipline of their own right in the middle of the twentieth century. Today, control theory and cybernetics are developing automatic devices applicable to physical and social systems. Departments and subjects on those topics are nowadays in most of the universities.

Self-Identification

Science

Although control systems of various types date back to antiquity, a more formal analysis of the field began with a dynamics analysis of the

centrifugal governor, conducted by the physicist James Clerk Maxwell in 1868. This generated a flurry of interest in the topic. But it could be said that the paradigm of control theory and cybernetics are self-identified as scientific disciplines since the early middle of the twentieth century.

Contemporary cybernetics began as an interdisciplinary study connecting the fields of control systems, electrical network theory, mechanical engineering, logic modeling, evolutionary biology, and neuroscience (► [Neuroscience](#)) in the 1940s. Early work sought to define and apply principles by which systems may be controlled. More recent work has attempted to understand how systems describe themselves, control themselves, and organize themselves. The ideas were soon related to biology. This branch of science concerned not only with control systems in electronic and mechanical devices but with its extension to useful comparisons and application to man-made and biological systems.

Religion

Cybernetics explores theories of self-reference to understand such phenomena as autonomy, identity, and purpose, and emphasizes with some human and social concerns. In fact, some cyberneticians seek to create a more humane world, while others seek merely to understand how people and their environment have coevolved.

Characteristics

Cybernetics is distinguished from other disciplines such as physics or chemistry because it treats not things but ways of behaving. It does not ask “what is this thing?” or “why does it behave like that?” but “what does it do?” and “what can it do?” Because numerous systems in the living, social, and technological world may be understood in this way, cybernetics cuts across many traditional disciplinary boundaries. The concepts which cyberneticians develop thus form a metadisciplinary language through which we may better understand and modify our world.

Related recent developments (often referred to as sciences of complexity) that are distinguished

as separate disciplines are artificial intelligence, neural networks, systems theory, and chaos theory, but the boundaries between those and cybernetics proper are not precise.

Relevance to Science and Religion

Control theory sees itself as a scientific endeavor with the aim to enhance the knowledge about where action by the system causes some change in its environment and that change is fed to the system via information (feedback) that causes the system to adapt to these new conditions: The system’s changes affect its behavior. In that broad sense, there is some growing interest in explaining human behavior from a mechanistic point of view (Mechanism) but the possible religious implications are weak.

Although there is a link between cybernetics, culture, and human behavior, very little work in cybernetics has centered on the application of this theory to human behavior. Instead, it has focused on technological advances in electronic and mechanical engineering.

Sources of Authority

As a branch of the engineering closely related to other empirical sciences, control theory finds the sources of authority in empirical data, repeatable experiments, and publication in peer-reviewed papers and textbooks. Their authority is self-derived by the peer-review process and from the underlying assumption of engineering that empirical data are the most reliable means of proving any statement about the behavior of any system.

As a second source of authority, there have been many good researchers who have influenced the establishment of these theories. Besides, there are many national and international scientific organizations such as The Cybernetics Society of the UK (2012) or The American Society for Cybernetics (2012). In addition to those societies, there are many scientific fora for addressing specific research topics such as the IEEE Systems,

Man and Cybernetics Society (2012), IFAC, etc. These organizations run their regular scientific meetings and in the majority have their own scientific journals. These organizations show increasing numbers of members.

Ethical Principles

On the one hand, control theory places emphasis on how the behavior of complex system is influenced by those very systems, trying to describe and explain it in a (mathematical) analytical way (► [Complex Systems](#)). It brings together theories and studies on communication and control not only in machines but in living organisms. From this point of view, there can be ethical implications that can be derived from the consequences of human actions, taking human being as complex systems.

On the other hand, disciplines that involve scientific research demand experiments that should be repeated and confirmed/refuted without making any harmful impact on humans and environment.

Key Values

Control theory and cybernetics have developed a concern for how a wide range of processes, including those involving people and work. Another key value of control is that of regulation, using feedback information from the system itself, in order to reach or acquire a desired behavior.

Conceptualization

Nature/World

Nature entertains all dynamic processes in the observable environment, including the interdependence relations between them.

Human Being

The human being is considered as a complex system with many regulation processes.

Control theory can model and analyze some of these processes.

Life and Death

Life is a dynamic process of a complex system, let us say human or any other kind of organic being. Death occurs when that process stops.

Reality

Reality is considered the physical world around us that humans can observe and measure.

Knowledge

The results of the scientific study of any process, in accordance with the feedback information that takes place in any regulation system.

Truth

The rules that so far explain the dynamic behavior of the processes.

Perception

The observations and measurements of any property or parameter that takes place in the universe. For a person to sense environmental changes there must be some reference point in his thinking, sensing, or perception which is addressed and then compared with some newer sensory information.

Time

Time is the fundamental dimensions of reality that makes a process change dynamically. Control theory aims to explain the changes in time of the behavior of a system.

Consciousness

There is not any conceptualization of this term from the control theory point of view.

Rationality/Reason

There is not any conceptualization of this term from the control theory point of view.

Mystery

There is not any conceptualization of this term from the control theory point of view. Even if this discipline could acknowledge in principle a place

for mystery, it means something that could be potentially understood applying adequate scientific knowledge.

Relevant Themes

With the development of new techniques, especially those that come from the artificial intelligence paradigm (► [Artificial Intelligence, General](#)), the control has evolved. From classical or conventional control to intelligent controllers, leaving behind the so-called modern control, this new approach tries to emulate intelligent functionalities of living beings. Ethical questions about the limits to science and technology arise from those advances. Critical issues such as intelligent machines, if machines will be able to reproduce the crucial capacities of human being, or if these intelligent devices will be able to think are posed. So far, it has been proved that automatic control means machines that learn, but how far will this go?

Besides, another ethical implication is that theoretically, every living system has some influence on every other system in large or small ways.

Finally, Wiener popularized the social implications of cybernetics drawing analogies between automatic systems and human institutions in his book *The Human Use of Human Beings: Cybernetics and Society* (Wiener 1954).

Conversation Analysis

Angela Cora Garcia

Department of Sociology, Department of Global Studies, Bentley University, Waltham, MA, USA

Related Terms

[Critical discourse analysis](#); [Discourse analysis](#); [Discursive psychology](#)

While there are no exact synonyms for conversation analysis, some scholars are working in closely related traditions such as discourse analysis or discursive psychology. The term conversation analysis originally was developed to apply to the ethnomethodological study of talk in interaction initially developed by Harvey Sacks (1992) and others, and which grew out of the ethnomethodological perspective developed by Harold Garfinkel (1967). The term conversation analysis has since come to be used by some others studying interaction from non-ethnomethodological frameworks as well. This terminological ambiguity does cause some confusion when searching for research in the area of conversation analysis and determining which research is ethnomethodological conversation analysis and which has its roots in other perspectives.

Description

Conversation analysis is a qualitative approach to the study of talk in interaction which developed out of the ethnomethodological perspective originated by Harold Garfinkel (1967). The goal of

conversation analysis is to discover how participants create social order and social organization through talk in interaction. Harvey Sacks (1984, 1992) decided to study talk because it was a form of social behavior that could be audio or video recorded, thus allowing for repeated direct observation of how participants acted and responded to the actions of others. While early research in conversation analysis primarily focused on informal conversations between acquainted persons (referred to as “ordinary” conversation), it has developed and expanded over recent decades to include studies of talk in a wide range of institutional and organizational settings, including talk in legal, medical, educational, political, and business contexts.

While what people are talking about, the “subject matter” of talk, is typically of interest both to the participants and to social scientists, for conversation analysts the subject matter of an interaction cannot be separated from an understanding of the procedures used to create the interaction. Participants display their understanding of the interaction via their actions, and use their knowledge of the shared procedures used to create and organize talk in interaction to interpret the actions of others. The sequential context of utterances (the words spoken in a turn at talk) is critically important for this interpretive process. The context includes the immediately prior utterance as well as earlier parts of the interaction. According to Garfinkel (1967), human action has the property of reflexivity; the interaction that is produced is also the mechanism through which participants create their social roles and the institutional context they are interacting within (Heritage 1984).

Sacks (1992) advised conversation analysts to ask “why that now” when trying to understand a particular segment of talk. Human action occurs in real time, in specific instances and occasions. In short, action is *situated action*, not decontextualized action. Thus when we examine human action, we discover that it is impossible to speak about “cause and effect” relationships between actions because the relationship between human action is not deterministic, and people decide how to respond to actions based on an

interpretation of what that action means in the context it occurs within.

Sacks (1984) notes that ethnomethodology is a “natural observational science.” By studying the methods and procedures people use to create interactions, we can develop a “grammar” of social action that explains the rules of constructing interactions in a wide range of settings and contexts. Sacks (1992) argues that interaction is orderly because people use shared methods for constructing their actions (see also Heritage 1987).
